tenance of life." In other words, the food we eat and the air we breathe do not alone supply all that is necessary for our existence. The radiant energy of the sun is equally necessary to life. We are constantly receiving and absorbing into our bodies light waves either from the direct rays of the sun or from the diffused light about us. These light rays perform an important function in maintaining the body health. Indeed, the cell life of the animal tissues can no more be continued in the dark than can the cell life of the plant when light is excluded from it. And yet the physiology of light has scarce been touched upon.

Sunlight, either direct or diffused, when falling upon our bodies is in part absorbed and in part is reflected from their surfaces. The darker the skin the more absorption takes place. In the African, practically 100 per cent. of the sun's rays falling upon his body is absorbed, while in the case of the blond a large percentage is reflected. The amount of light energy which reaches the clothed body is not great as practically all the rays are absorbed by the clothing worn. Hence, merely sitting or walking about in the sunshine falls far short of what is meant when we speak of "light treatment" or "heliotherapy."

The sunlight absorbed by the body represents a tremendous energy which becomes a part of the vital assets of the individual. Much of this light energy is taken up by the blood and is carried by it to every organ within the body. Many years of experience by numerous investigators have shown that this energy is not only a real power for good in the maintenance of health but is applicable to the treatment of a wide range of diseases. Indeed, it was well known to physicians of the earlier centuries that sunlight was one of the most efficient remedies at their command. It was in general use as a therapeutic agent in that day and solaria were built into the homes of many of the wealthy people. Among some primitive peoples, as in sections of South America, sunlight is still used in much the same way it was centuries ago.

But sunlight as a remedial agent was for hundreds of years almost wholly abandoned by the medical profession and it has been only during the last decade that attention has again been directed to it. Sufficient data are now at hand to enable us to make a partial list of the affections to which sunlight may profitably be applied.

The most noticeable results perhaps have been obtained in the treatment of rachitic children and of children suffering from various forms of bone tuberculosis. Rollier of Switzerland, most notably, has obtained marvelous results in this class of patients. He exposes the entire body surface of these children to the sunlight for several hours each day. Almost without exception they at once begin to take on weight and to gain in strength and soon are well on their way to complete recovery.

In anemia very similar results are obtained. Many of these patients have been closely housed, often in homes that are dark, their nutrition is bad, they are in need of just such an invigorating tonic as sunlight proves to be. Their blood is lacking in hemoglobin and this the light produces just as in the plant cell the sunlight brings the bright green chlorophyl.

For like reasons sunlight proves the remedy par excellence in diseases of debilitating nature, in tuberculosis and other wasting diseases, in neurasthenia, and in convalescence from disease. Such

patients properly exposed to the direct rays of the sun usually respond most favorably to the treatment.

In surgical tuberculosis, and especially after operative procedures to relieve the same, and where healing is slow or refuses to take place, sunbaths offer the best prospect for successful treatment. Wounds and injuries of all kinds heal promptly under the influence of direct sunlight. Solaria are now established in many places near the battle fronts in Europe to give to the wounded soldiers the benefit of this rediscovery of a once forgotten successful method of treatment. It not infrequently happens that where the *x*-ray has long been tried without success a change to sunlight is quickly followed by relief.

In skin affections sunlight promises brilliant results. As many of these diseases are of bacterial origin the explanation is not far to seek. Sunlight is the most efficient bactericide known; the light kills the bacteria and the skin heals by natural processes. In lupus, eczema, psoriasis, and other skin lesions of bacterial origin, results are both prompt and gratifying.

In cervical adenitis, and upon surgical wounds made for the relief of cervical adenitis, the light exercises an influence of great value. Particularly is this true when a strong concentration of light by means of lenses is used upon the neck, followed by a general sunbath in which the entire surface of the body is exposed to the direct rays of the sun for an hour or more each day.

Heliotherapy is the treatment of disease by means of sunlight falling directly upon the nude body of the patient, and by the use of sunlight concentrated by means of convex lenses or by concave reflectors and directed upon certain local areas of the body which may be in need of treatment. In cervical adenitis, for example, the strongly concentrated light is played upon the glands of the neck for half an hour and then a general sunbath is given afterwards.

Sitting or walking in the sunshine with the body fully clad may be of a little value but it is not heliotherapy. In the treatment of disease by sunlight not even the thinnest clothing is permitted to intervene, as the clothing absorbs the sun's rays and the full effect of the light is not obtained. Whenever possible the entire body is exposed to the sunlight, the head only being protected from it.

The patient must very gradually become accustomed to the sunlight, otherwise disagreeable burns may be produced and blistering may occur. The usual method in initiating the patient to treatment is by the exposure of the feet and legs to the light for ten or fifteen minutes on the first day; on the second day the feet, legs, and thighs are exposed for fifteen minutes; on the third day the lower portion of the body is added, and on the following day the entire body, with the exception of the head, is exposed for the same length of time. The daily treatments are now gradually increased in length of time until an hour or more is passed with the full body exposed to the light. In winter the patient may thus lie in the sunshine for a number of hours each day.

No matter what the form of malady for which treatment is given the exposure of the body is total; in this manner only may all the blood circulating on the surface of the body be flooded with the sunlight.

The revival of the "sun cure," added as it now

is to the discoveries made during the past quarter of a century in the field of bacteriology, means much toward the relief of many diseases whose causes are of bacterial origin.

RETROVERSION AND RETROFLEXION.

By ADOLPH JACOBY, M.D.,

NEW YORK.

CLINICAL ASSISTANT GYNECOLOGIST, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

RETROVERSION is that condition in which the uterus and cervix are turned from their normal position in the pelvis, revolving about the internal os as an imaginary pivot, the body tilting backward and the cervix forward, without changing the angle formed by the junction of the body and the cervix.

Retroflexion is that condition in which the body only is bent backward, the cervix remaining in its normal position, thus changing the normal acute angle of ante flexion between the cervix and body, to a straight angle or even to an obtuse angle.

These two conditions should not be confused with retroposition of the uterus where the cervix and body are both pulled backward toward the sacrum without changing the angle between them.

The great majority of cases of retroversion are associated with a greater or lesser degree of retroflexion, so it is advisable to consider these two together.

It is customary to divide retroversion into three degrees. The first degree in which the fundus points toward the promontory of the sacrum; the second degree in which the fundus points backward towards the hollow of the sacrum; and the third degree in which the fundus points downward towards the coccyx, being completely upside down. It is readily conceivable how there may be any number of intermediate degrees, depending upon the position of the fundus.

Retroversion is fairly common among gynecological patients. Of 300 consecutive cases, 109 or 36 per cent. had retroverted uteri. Of this number 45, or 15 per cent. of the total number of patients examined, were pure cases of retroversion, that is, uncomplicated by any other pelvic disorder; 30, or 10 per cent. were associated with a posterior parametritis, 17 or 5.5 per cent. with diseased adnexa; 9, or 3 per cent. with both a posterior parametritis and a descensus uteri, and 8, or 2.5 per cent. with a descensus uteri.

The cases of pure retroversion are very often congenital, discovered only during a bimanual examination. Of the acquired factors prominent in the causation of retroversion, most frequent are lacerations of the pelvic floor during childbirth, with subsequent subinvolution of the uterus and ligaments, aided probably by tight abdominal binders, dorsal decubitus, and pressure of the abdominal contents. This causes the heavy relaxed uterus to tip over backward and stay there, because of its weight and the pressure upon it from above and in front. Once the uterus is retroverted, the intra-abdominal pressure on the anterior wall tends to aggravate the condition, so that retroversion, if left alone, always becomes more marked, instead of remaining stationary or showing improvement.

Inflammatory adhesions from the sacrum to the fundus, following a pelvic perimetritis or parametritis, usually causes the fundus to be drawn backward. This produces an adherent retroversion which is very difficult and painful to replace. An

overdistended bladder or a large cyst of the ovary—usually dermoid—growing in front of the uterus, may push it backward. Among other causes of retroversion may be mentioned growths on the back of the uterus drawing it downward and backward by their weight, falls, or blows on the abdomen, or heavy lifting; these last, however, do not occur very often.

In some of the text-books of gynecology, backache is mentioned as the most prominent symptom complained of by patients having retroversion. Now in our series of 109 cases, in not one of the 45 pure cases of retroversion was there complaint of backache, most of them being diagnosed as retroversion during the routine examination of all cases referred to the clinic. On the other hand, all of the 30 patients with retroversion associated with a posterior parametritis, did complain of backache. In all of the 9 cases associated with posterior parametritis and descensus uteri, there was complaint of backache and a bearing down sensation. In the 8 cases associated with descensus, none of the patients complained of backache. All complained of a bearing down sensation. In the 17 cases associated with diseased adnexa, none complained of backache; all complained of pain in one or both sides of the lower part of the abdomen.

Reviewing these symptoms as associated with their pathological findings, it becomes evident that retroversion, unless associated with a posterior parametritis, does not give rise to backache. In a previous article, it has been shown that backache is a constant complaint of patients suffering with a posterior parametritis. It is therefore very evident that the backache depends upon and is caused by the associated complications, and not by the retroversion. The same may be said for the pain in the lower part of the abdomen and the bearing down sensation, namely that they are not caused by the retroversion, but by the accompanying pathological complications. In 50 of the cases a leucorrhœal discharge of greater or lesser amount was present. Of this number 10 were in the pure cases of retroversion, and 40 were in those with complications. Irregular or profuse menstruation occurred in 26 instances, 9 in the pure cases and 17 in the complicated. Frequency of urination occurred in 10 instances, 2 in the pure cases and 8 in the others. In 15 instances, constipation was a marked feature, 4 in the pure cases and 11 in the complicated.

It may thus be seen that the symptoms of retroversion are not very pronounced or numerous, and depend in a large measure upon, and are greatly aggravated by, the pathological conditions associated with it.

It is also clear that backache or a bearing down sensation is never associated with retroversion *per se*. This is important in the consideration of the treatment of retroversion.

The diagnosis of retroversion usually offers very little difficulty. A bimanual examination as a rule readily reveals the position of the fundus and its relation to the cervix. In very obese patients or those with rigid abdominal walls, in whom the fundus cannot be made out, we can, as a rule, feel the lower portion of the body of the uterus, just beyond the cervix, with the fingers of the internal hand. From this finding we can picture the position of the remainder of the body, from our knowledge of its anatomical relationship and contour. It is rarely necessary, nor is it advisable, to intro-

duce a sound to determine the direction of the body of the uterus. A rectal examination occasionally aids in the determination of the position of the fundus, and a combined rectal and vaginal examination helps to disclose the presence of adhesions between the fundus and the sacrum.

The treatment of retroversion depends necessarily in a great measure upon the associated conditions present. For the cases of pure retroversion treatment is rarely necessary, as they do not cause sufficient annoyance to warrant interference. Before treatment of the retroversion itself can be instituted, the accompanying complications must be treated and relieved. For posterior parametritis, treatment as outlined in a previous article—glycerin and gauze packing of the vagina and hot douches—is very effective. Any adhesions present must be broken up, if possible, by gentle manipulation of the fingers in the posterior fornix. Very much can be accomplished by this daily massaging of the fornix, in the stretching of old adhesions and breaking up fresh ones, thus allowing the uterus to be subsequently reduced to its normal position. Disease of the adnexa must be treated according to its extent, by glycerin and vaginal gauze packing plus hot douches, or by operation. The further treatment of retroversion is either by reduction of the uterus and its maintainance in position by means of mechanical support, or operative measure.

Before mechanical support can be introduced, the uterus must first be brought back to its normal position in the pelvis. This is done during a bimanual examination, with the patient in the dorsal position, by exerting pressure backward on the anterior surface of the cervix with the internal fingers, and with the external hand on the abdomen, getting behind the fundus and lifting it forward. Another method which may be used, is one finger in the anterior fornix pushing the cervix backward, and the other in the posterior fornix pushing upward on the fundus at the same time; or both fingers in the posterior fornix pushing the fundus upward. The external hand in either case is used to get behind the fundus and lift it upward the same as before. The knee chest position may be used to aid in the reduction. If this does not succeed traction on the cervix by a tenaculum may be helpful. The administration of an anesthetic may be necessary to relax the abdomen and help in reducing the uterus. It is, as a rule, not advisable to use a sound in the uterus or the various uterine repositors for the correction of a retroversion, as they produce too much trauma and may subsequently give rise to infection.

After correcting the malposition, the uterus is held in place by a properly fitting and properly applied Hodge or Smith pessary. For retroversion associated with a descensus uteri, a Gehrung pessary is very efficient. One thing to be remembered in the use of the pessary is that it should never be introduced as long as there is an inflammatory condition present in the pelvis.

The operative treatment of retroversion, which I do not intend to discuss, usually comprises some form of suspension or fixation of the body of the uterus abdominally or vaginally, or the shortening of the round ligaments. It is well to remember that operation is rarely necessary for uncomplicated retroversion, or retroversion part of a general enteroptosis, and when performed is required by the conditions associated with the retroversion.

To conclude I wish to lay special emphasis upon the chief point brought out by this article, namely, the scarcity of symptoms associated with retroversion, and the complete absence of that symptom at one time considered so constant, to wit—back-ache.

AN IMPROVED FLEXIBLE ESOPHAGEAL BOUGIE.*

BY ROBERT COLEMAN KEMP, M.D.,

NEW YORK.

PROFESSOR OF GASTROINTESTINAL DISEASES AT THE BORDMAN UNIVERSITY MEDICAL SCHOOL.

THE writer has frequently called to the attention of his students that instrumental examination of the esophagus with bougies is by no means always a safe procedure, and in his book on gastrointestinal diseases states that the safest method is by the use of soft-rubber stomach tubes of various calibers. This is particularly true for the novice.

Even during the examination of an apparently normal esophagus, one may find partial obstruction to the entrance of the instrument from adenoid tissue at the base of the pharynx, or from anterior curvature of a cervical vertebra. I have had such experiences.

The bougie with a whalebone stem in a single piece, such as is employed by H. S. Plummer, or the divisible whalebone bougie of Einhorn, are probably the most popular instruments. Though they are denominated as flexible by some, they are not sufficiently so to eliminate all danger. There are numerous flexible esophageal bougies, notably those of Sippy, Lerche and a special one of Plummer's, and also imported instruments of soft rubber. As far as I can determine, my own instrument most nearly resembles that of Lerche (*Jour. Am. Med. Assn.*, July 29, 1911), consisting of a flexible wire shaft, covered with rubber and with perforated olives so that they can be threaded on a silk guide. Time does not allow me to refer to other originators of flexible esophageal bougies, so I must apologize in advance, in order to avoid controversy. The idea, therefore, is by no means original with the writer. Every good horse or dog owner believes that his animal possesses some peculiar virtues, and I am merely so far opinionated in regard to my own instrument. I believe there are a few new features.

The bougie, herein described, has a small stem, about the diameter of 11 French, made of wound flexible wire, hollow, and covered with rubber, to which olives of various sizes can be screwed. There are six olives in the set. They are perforated obliquely so that they can be threaded on a silk-thread guide if such should be required. (See illustration.)

It is well known that slight or commencing stricture of the urethra can be the more readily determined by flexible bougies of various calibers. The flexibility apparently increases the delicacy of the touch and renders a more ready appreciation of any irregularity, or narrowing of the canal, even though it be slight. The same holds true in examination of the esophagus by means of the flexible bougie and even small sensitive ulcerative areas can be the more readily appreciated.

*Read before Medical Association of Greater City of New York, Jan. 17, 1916.

Other methods, however, have also been suggested for the determination of commencing stenosis. Bassler, for example, employs radiography, after first plugging the cardiac orifice of the stomach with an inflated bulb and filling the esophagus above the plug with barium, or bismuth; while others have inserted into the esophagus sacs of gold-beater's skin, or animal membrane, and after filling them with barium or bismuth have radiographed the esophagus. (W. H. Stewart: "Advanced Röntgen Technique in the Diagnosis of Esophageal Lesions," *American Journal of Röntgenology*, October, 1914.)

Local anesthesia with cocaine or eucaine is rarely necessary for the introduction of the flexible instrument and it can be inserted with the head in the natural position (*i.e.* without extension) and with but little disturbance.

There are three stylets of different caliber made of piano wire, furnished with each instrument. After the sound has entered the esophagus and passed to the point of stricture, if it is desired to stiffen the instrument in order to pass through the stricture or to calibrate it, a stylet can be inserted with the head still in the natural position. Three degrees of stiffening can be secured. Complete pro-

Flexible esophageal bougie with inch markings; stylet; perforated olives.

tection to the stylet wires is afforded by bulbous tips, so that their points cannot possibly penetrate the wire tube forming the shaft of the instrument. It is possible to secure slightly stiffer stylets, or a bougie with a stem of larger diameter for still thicker stylets.

The rubber tube covering the wire shaft has upon it circular markings at inch intervals, starting from the point of attachment of the olive. The distance of a stricture from the teeth can be sufficiently closely estimated by computing the number of marks (rings) from the olive to the teeth plus the length of the small metal fitting and about half the length of the olive small enough to just pass the obstruction. In the case of a very tight stricture which the smallest olive would not pass, the entire length of the latter should be added, to properly compute the distance. One can bend the instrument and measure the unmarked sections noted, by means of one of the marked inch spaces, so that no tape measure is required.

The ingestion of sweet oil previous to the passage of the bougie is an excellent procedure. The value of olive oil injection into the urethra previous to the passage of urethral bougies is well known and the same is true of the esophagus. For example, float 3ss of sweet oil on an ounce of iced water,

which last also helps to anesthetize the parts for a moment, and have the patient drink the same just before the passage of the esophageal bougie. If the tongue be immediately touched to a pinch of salt it will relieve the disagreeable taste of the oil.

It is always advisable to make a digital examination of the lower pharynx to determine whether adenoid tissue, vertebral deformity, a new growth, or any obstruction is present, which would interfere with the passage of the instrument. This type of bougie the writer believes to be safe for the examination of children.

103 EAST FIFTY-SEVENTH STREET

EXPERIMENTAL STUDY OF THE EFFECT OF EMETINIZED BLOOD ON THE TYPHOID BACILLUS.

By MARCUS BEEKMAN, M.D.,

NATCHEZ, MISS.

DIRECTOR CLINICAL LABORATORY OF THE NATCHEZ SANATORIUM.

It was my pleasure to read recently with great interest an article on a treatment for typhoid fever which, if the results as stated could be substantiated by other investigators, would rank among the great medical achievements of modern times. The article I refer to was on "The Abortion of Typhoid Fever with Emetine Hydrochloride," by William L. Frazier, M. D., appearing in THE MEDICAL RECORD, March 20, 1915.

Realizing the great advantage of such a treatment which, according to the author, "in only six cases of a series of eighty-two treated by injections of Emetine did the fever run longer than four days after the treatment was begun, and none of these six extended over a period of more than six days," I decided to try the matter from a purely laboratory point of view. I therefore secured the permission of one of the local physicians to carry out my experimental work with one of his patients. The patient was under the care of competent pupil nurses in a private institution during the entire course of the experiment, and the records show that the treatment was carried out to the letter. I will omit the history and description of the present illness as my work was not undertaken with any idea of showing the effects of emetine on the course of typhoid fever. In fact, there is still considerable doubt in my mind whether the case was actually one of typhoid or of some other disease. My work was undertaken solely for the purpose of showing whether emetine did or did not produce a bactericidal condition of the blood when given according to the method used by the writer of the article referred to above.

I therefore bled the patient, after which treatment was begun. This blood was allowed to clot, the clear serum collected, and the following dilutions made: 1:2, 1:5, 1:10, 1:20, 1:50, 1:100, 1:200, 1:500, 1:1000, 1:2000, 1:5000, 1:10,000, 1:100,000, 1:500,000. By a dilution of 1:2 I mean one part of serum with sufficient broth to make two parts; by 1:5 I mean one part of serum with sufficient broth to make five parts, etc. Somewhere in the neighborhood of two cubic centimeters of each dilution was placed in a test-tube and each tube in the series inoculated with a loopful of a 14-hour broth culture of bacillus typhosus. These were incubated at 37 C. for 24 hours. At the end of this time all of the dilutions showed a heavy growth of the bacilli. At the same time that this test was set up,

a Widal test was also done with the serum in dilutions of 1:20, 1:40 and 1:60, all of which were negative at the end of one hour. There was a pseudo-reaction in the dilution of 1:60 with some clumping and many actively motile bacilli.

Following the drawing of this blood emetine hydrochloride was given subcutaneously in one-half grain doses every six hours until twenty doses had been given. Exactly three hours after the twentieth dose, blood was again drawn by venous puncture and an identical set of dilutions with inoculation as before was set up. After this had been incubated for the same length of time all of the tubes again showed a heavy growth of the typhoid bacillus.

I therefore came to the conclusion that the subcutaneous administration of emetine hydrochloride in one-half grain doses every six hours does not impart any bactericidal properties to the blood, at least so far as the typhoid bacillus is concerned.

One case and one observer, however, are not sufficient on which to base any definite conclusions, and I therefore hope that other observers will investigate the matter and publish their results. Certainly any treatment as simple as that which has been laid down by the originator of this therapeutic measure and which gives such very gratifying results should not be passed by without further investigation.

Medicolegal Notes.

Contract for Physician's Services—Insurance.—A corporation entered into separate contracts with, among others, a physician, whereby the physician agreed to sell his services to such persons as the corporation might direct for a consideration to be paid him by the corporation. Venereal diseases, chronic and incurable diseases, and major surgery were excepted. The corporation then contracted with its subscribers to procure for them medical service free (with the exception that the subscriber should pay the physician one-half the regular fee in obstetrical cases). The contract provided that the agency "assumes no liability for the breach of any one or all of said contracts. The agency agrees, however, that in the event of a breach, it will use its best efforts to procure other persons or firms to offer the same or similar service." The insurance commissioner of the State of Washington, where the corporation was doing business, instituted an action to have its franchise forfeited because it did not comply with the insurance statutes. The question to decide was whether the company was actually doing an insurance business.

The essential elements of an insurance contract are: (1) An insurer; (2) a consideration; (3) a person insured or his beneficiary; (4) a hazard or peril insured against whereby the insured or his beneficiary may suffer loss or injury. It was held that there was, under the terms of the contract, no hazard or peril whereby the purchaser of the contract might suffer loss or injury, which the company insured against, and therefore the principal essential to an insurance contract was lacking. It did not guarantee that the physician would perform the services agreed upon. It was therefore not engaged in the insurance business.

The court distinguished the case from the so-called *Physicians' Defence Company Cases*, 199 Fed. 576 and 100 Minn. 490, where the company agreed for a stated consideration paid to it by a physician to defend the physician against "all civil suits for damages for malpractice, based on professional services rendered by himself or his agent during the time of the contract at its own expense, not exceeding \$5,000," subject to certain defined conditions. This contract was held to be one of insurance. There was therefore in all cases of this kind a contract for indemnity against a hazard which might cause the physician loss.—*State v. Universal Service Agency*, Washington Supreme Court, 151 Pac. 768.

THE PRESENT STATUS OF THE ABDERHALDEN REACTION.

THE theories upon which Abderhalden based his method for the detection of specific ferments in the blood serum were so attractive and fitted so closely with many already established ideas concerning the body functions, that they were at first accepted very generally. His experimental data were apparently quite complete and very convincing. The reaction based upon these theories immediately became very popular, and about it there has grown up a literature which, even in the few years of its existence, has become so great it is impossible for any one man to become wholly familiar with it. Gradually the first enthusiasm wore off and dissenting voices became audible. These latter grew in volume, and lately the majority seem to have agreed that the reaction is of little practical value. The technique of the reaction is exceedingly difficult, and Abderhalden has maintained that contradictory results are due to faulty application of the methods on the part of the dissenting laboratory workers. But some of the objectors have been careful experts, and the wholesale denial lacked conviction. Repeated efforts have been made to simplify the reaction so that its results might become more reliable, and the most significant of these has been the substitution of the amino nitrogen determination in the dialysate in place of the delicate ninhydrin test. An additional advantage obtained by the use of this method was that an exact quantitative estimation could be made and the unreliable comparison of colors was completely avoided.

In the most recent report on the use of this method, Van Slyke, Vinograd-Villchur, and Losee (*Journal of Biological Chemistry*, 1915, xxiii, 377) present the results of the examination of blood sera from pregnant women and from numerous non-pregnant controls. Their conclusions are apparently justified by their careful work and are worth quotation. "Practically every serum, whether from a pregnant or a non-pregnant individual, showed protein digestion when incubated with placental tissue prepared according to Abderhalden. The range of individual variation in proteolytic activity was wide. The range covered by most of the normal sera was, however, identical with that covered by the majority of the pregnant sera. . . . There is a tendency for the results from the pregnant sera to average somewhat higher than those from non-pregnant. The

difference, even in the averages, is not great, however; and the individual variations of both pregnant and non-pregnant sera make the results from both overlap so completely as to render the reaction, even with quantitative technique, absolutely indecisive for either positive or negative diagnosis of pregnancy. . . . It appears that nearly all human sera can digest certain coagulated tissue proteins to some extent."

Bronfenbrenner has approached the problem from another angle, and we have already had occasion to mention his theory in explanation of the reaction. In his latest paper on the subject (*Journal of Laboratory and Clinical Medicine*, 1915, i, 79) he reviews the technique and shows that its complexity is so great that even if the reaction were conclusive, its usefulness would be greatly restricted. He emphasizes his demonstration that the digestion of the tissue is due to the action of the normal proteolytic ferment of the blood serum and not to a specific ferment and shows that it is possible to obtain a positive pregnancy reaction with male sera merely by increasing the amount of placenta used. He is of the opinion that it may be *relatively* specific within certain quantitative limits, but ceases to be outside these limits. He reiterates the argument that the rapidity with which these ferments appear after immunization in experimental animals, militates against the possibility of their being really specific ferments. The test is due to the absorption of antiferments in the blood serum by the tissue used, and involves the action of complement and may be somewhat similar to the stalagmometer reactions of Ascoli. He still maintains that satisfactory results may be obtained in a certain number of cases, but insists that the method must be performed by a high class worker, specially trained in this special reaction, and concludes that at present the reaction has merely a scientific interest. Its value as a routine method of diagnosis is very, very small.

It seems worth while to call attention to the conclusions reached in these two laboratories, for the test is no doubt quite extensively used through the medium of diagnostic laboratories. A careful consideration of all the evidence presented in these articles leads one to the inevitable conclusion that the Abderhalden reaction can be of almost no value to the practitioner as a method of diagnosis. If it has any place at the present time it is as a possible aid to the expert immunologist in the working out of special problems, and even that place is not well defined or accepted. It has served, however, to stimulate the study of the fermentative activities of the body fluids, especially the blood, and has therefore played its part in the general scheme of things. The part being played, it is now apparently time for the player to retire.

COMPULSORY INSURANCE AND THE MEDICAL INCOME.

IN an address before the Congress on Medical Education, Public Health, and Medical Licensure which met at Chicago on Feb. 7, Dr. Otto V. Huffman, formerly Secretary of the New York State Board

of Medical Examiners and Secretary of the Federation of State Medical Boards of the United States, advocated a new plan for the regulation of the practice of medicine in this country. He pointed out that originally the first licensing boards were created simply to examine the apprentice—trained physicians and surgeons, who had not attended any medical college, and that medical college graduates were given the license without examination just as in many foreign countries to-day. About thirty years ago, because of sectarian medicine it became necessary to make an all-inclusive requirement for the license, and for the sake of trying to appear just to all applicants, all were required to pass the same examination, regardless of their qualifications and training. In recent years there has been a gradual movement toward the recognition of the educational basis for any qualification to practise medicine. This has meant the more and more careful looking into the standard upheld by a medical college, and even by the high schools and colleges whose credentials it recognizes in granting admission to students. With all of this activity on the part of many individual State boards of medical examiners, it is no wonder that as yet there is no uniformity or concerted action. There are many differences over minor details and that is why the long-desired reciprocity in medical licensure is delayed. The State boards retaliate against one another with absurd requirements. To break this up the plan of a national examination and licensure has been advocated, but Huffman does not seem to favor this, urging rather that the Federation of State Medical Boards, *i.e.* a majority of the States, should agree upon a common standard, and give the license to all who came up to this standard without making them take a State board examination. This is the way it is done in some foreign countries, the State being quite content with the examinations given by an approved faculty. For those who have not received their training in the prescribed way, thorough practical State board examinations should be provided.

In some instances there are grounds for the suspicion that the State board aims not to allow the medical profession in its State to become overcrowded. To meet this phase, which always comes up sooner or later in any discussion of the question of how the practice of medicine should be regulated, Dr. Huffman recommended compulsory sickness-insurance as the best way for putting the practice of medicine on a sound economic basis. If his figures are true, they are astounding. According to them, the medical profession is receiving only one-ninth of what the U. S. Industrial Relations Commission computed its services to be worth. The average income of a physician is only \$500, whereas it ought to be \$4,500. Compulsory sickness-insurance, Dr. Huffman said, could be introduced in this country on a national scale and without any of the drawbacks of the European systems. It should provide only the services of a doctor and leave the matter of health insurance, with its cash benefits, to the private companies. In this way the medical profession would not be hampered and could work freely along preventive lines. In

fact its interest would be more largely concerned with the prevention of disease or disability and in no way could it be influenced by the patient's concern over cash benefits. The insurance companies would, of course, have their own referees to pass on cases. If the British plan were adopted, a doctor could refuse to carry a panel and limit his practice to patients with incomes of \$1,200 or over, as these would not come under the scheme of compulsory insurance. And likewise wage earners compelled to pay the insurance tax could exercise choice—they could choose any doctor carrying a panel who would accept them. To prevent electioneering for a large panel, it could be limited to 2000. The insurance companies would probably not oppose the plan because it does not call for cash benefits.

There is so much that is entirely new in this scheme, and so much that seems advantageous, that every physician ought to give it careful consideration in order that it may be wisely matured. Certainly the present plan of medical licensure is not exactly satisfactory, nor is the present economic situation of the practice of medicine. The medical profession is doing too much for nothing. It is said that in New York City alone, 4,000,000 patients, from whom the medical profession does not receive a cent, are treated annually.

REGISTRATION OF BIRTHS AND DEATHS AND NOTIFICATION OF DISEASE.

UPON the compilation of statistics depends, to a large extent, information as to the prevalence of disease and the morbidity and mortality rates arising therefrom. That this information should be as accurate as possible is, of course, of the first importance, and it therefore behooves medical practitioners to see to it that they know exactly how to register births and deaths and to report sickness. The system of registration is by no means perfect and is open to criticism in many respects, but matters would be greatly improved if practising physicians were better acquainted with the modes of gathering this kind of information.

In *Public Health Reports*, January 14, 1916, this subject is discussed at some length, and it is pointed out that it is the bounden duty of the physician to know the purposes of the registration of births and deaths and the notification of the occurrence of preventable diseases, and the uses made of the records. He should also know thoroughly the legal requirements of his community in regard to these matters. A full explanation is given of the manner in which the physician should proceed in attesting to the registration of births and deaths and the value of properly carrying out the procedure is emphasized. The mode in which the reporting of sickness should be done is explained and the following summary of the uses of morbidity reports is appended: "(1) In the communicable diseases, morbidity reports show the occurrence of cases which constitute foci from which the disease may spread to others, as in scarlet fever, typhoid fever, tuberculosis, or yellow fever, and make it possible to find the previously unrecognized cases and to take proper precautions to protect the family

of the patient, his associates, or the community at large. (2) In some cases morbidity reports make it possible to see that the sick receive proper treatment, as in ophthalmia neonatorum, diphtheria, and, in certain cities, tuberculosis. The reporting of cases of ophthalmia in the new-born makes it possible to save the sight of some infants who would otherwise not receive adequate treatment until after much damage had been done. In diphtheria the health department can be of service in furnishing antitoxin. Some cities furnish hospital or other relief to consumptives who would otherwise be without proper treatment. (3) In diseases that are not communicable, such as those due to occupation or environment, reported cases show the location or conditions which are causing illness or injury. This makes it possible to remedy the faulty conditions, so that others may not be similarly injured. (4) In certain diseases, of which the cause or means of spread is unknown, morbidity reports show their geographic distribution and varying prevalence and the conditions under which cases occur. This information has great potential value in attempts to ascertain their causes and means of spread. (5) Reports of the occurrence of disease are necessary to show the need of certain sanitary measures or works and to control and check the efficiency of such measures or works when put into operation. In pulmonary tuberculosis such reports show the number of consumptives in the community and the need of sanatoria. In malaria they show the prevalence of the disease, the need for drainage and other antimosquito work, the efficiency of such work when in operation, and when a change in the prophylactic measures is required, or additional ones are necessary. In typhoid fever they show faults in the water supply or in the control of the production and distribution of milk, or in the disposal of excreta in special localities. (6) Morbidity reports, when recorded over a period of time and properly compiled, become a record of the past occurrence of disease. They show the relative prevalence of disease from year to year and under varying conditions. They show the effect of the introduction of public health measures and of sanitary works. They give a history of disease not obtainable in their absence."

The practising physician should be cognizant of his responsibilities with respect to the registration of births and deaths and the reporting of cases of the notifiable diseases. In this field he owes a duty to the community, to the individual child, and to its parents, which duty he alone can perform. In the prevention of disease it is essential that registration of births and deaths and the reporting of notifiable diseases should be performed promptly and accurately and, as said before, it is incumbent on the practising physician to see that neglect to do this does not imperil the health and welfare of the people at large.

"AQUARIA VIVA."

THE term "living" or "human aquarium" is used to some extent to denote the showman who swallows water by the quart, some of which contains small fish, tadpoles and frogs, which he rejects at will

by compressing his stomach. Recently a despatch in a metropolitan daily stated that a performance of this sort had been stopped by a local humane society, doubtless rather from principle than because of any actual animal suffering. At a session last summer of the General Medical Societies of Cologne (*Muenchener medizinische Wochenschrift*, November 23) an "aquarium vivum" was presented to the society, not indeed as a medical curiosity, but because in swallowing a handful of nails, one had got into the trachea (evidently he combined the roles of "aquarium" and "ostrich"). His stomach extended three fingers' breadths below the iliac crest. He was accustomed to swallow from 10 to 14 liters of water, and allowed 5 frogs and 3 goldfish to remain in his stomach for 20 minutes. Some of these were dead when rejected, others living, but the latter soon succumbed. He also swallowed his watch without effort—it was 25 cm. broad—on the chain, so that he could extract it at will. Finally he plunged his cane into his stomach and allowed it to remain for some minutes. Unlike the old-time sword swallower, these artists make no bones of their stunts—the sooner done the greater the renown.

CHRONIC RECURRENT TETANUS.

IN France, after trench fighting had continued for some little time, tetanus of the acute and hyperacute type was extremely rife. The treatment of these forms of tetanus by means of antitetanic serum and their prevention by injections are said to have been so highly successful that the affection is now practically extinct. Chronic recurring tetanus, however, although rare, is observed now and then at the French seat of war. In the *Medical Press*, January 12, 1916, Dr. Albert Mouchet, Chief Surgeon to the Auxiliary Hospital No. 26, at Orleans, discusses this form of tetanus from the clinical point of view. A case is reported in which a piece of shell had been left in the tissue and it was found that tetanus recurred from time to time until this had been extracted. Mouchet points out that the great lesson to be drawn from this case is that from the moment that tetanus makes its appearance in a case in which the projectile is still in the tissues, it must, if possible, be extracted with the greatest promptitude. For this purpose early radioscopic examination is indispensable, after which no time should be lost. The injection of antitetanic serum, free opening up of the wound, and extraction of the projectile constitute the tripod therapeutics on which treatment of such wounds must be based.

News of the Week.

Fresh Air Home.—The Fresh Air Home at Dumont, N. J., which was opened on June 1, 1915, for the purpose of furnishing summer vacations to the children of tuberculous families living in crowded tenement districts in New York, reports that during the summer seventy-four children, ranging in age from five to fourteen years, were cared for. Both girls and boys were taken, and all showed a marked increase in weight and an improvement in general condition as the result of living under proper hygienic conditions. The home is conducted as an adjunct of the social service work of the Yorkville Tuberculosis Clinic.

Children's Homes.—The Department of Health

has recently completed a survey of homes for children located in New York City, including a careful inspection of the plumbing, heating, lighting, and ventilation of the institution, the cleanliness of the premises and of the inmates, the diet and methods of cooking, the character of the clothing, and the care of the sick. Within the five boroughs of the city there are eighty-four institutions of this class, all of which were inspected, with the result that 1,443 recommendations were made by the Bureau of Child Hygiene, and of these 654 were promptly complied with. The other recommendations were largely of a structural nature, so that time was necessary before they could be entirely satisfied. Of the children themselves, 56 per cent. showed some physical defects; the treatment of these during the past year was, however, very satisfactory, more than two-thirds of the conditions being entirely remedied, and only 5 per cent. remaining untreated. In the opinion of the officials of the Department of Health the conditions disclosed by the survey were most satisfactory, the institutions all showing great willingness to comply with the recommendations made.

City Death Rate.—During the week ending January 29, the death rate in New York was 16.46 per 1,000, as compared with 13.64 for the corresponding week of last year, the total number of deaths being 1,812 and 1,460, respectively. Although the acute infectious diseases caused fewer deaths during the week than during the same week of 1915, the deaths from influenza, bronchitis, and pneumonia numbered 435, as compared with 261, and there was a considerable increase also in the deaths from heart and kidney diseases. The highest mortality occurred among the adults of the population, as has been the case in the last few weeks, the death rate for children under five years of age being less than for last year. The death rate for the first five weeks of 1916 was 16.47, as compared with 14.64 for the corresponding period of last year.

Dr. A. J. Barker Savage has been appointed superintendent of the Broad Street Hospital, New York, and of the Sea Gate Reception Hospital, Coney Island.

Gift to Charity.—A bequest amounting to a few thousand dollars was made to Society of Servants of Relief for Incurable Cancer in the will of the late Kate Gilgan of Central Islip, N. Y.

Street Accidents.—The National Highway Protective Society reports that during January, 1916, 34 persons, of whom 13 were children, were killed on the streets of New York City, 22 by automobiles, 7 by trolleys, and 5 by wagons. Eighteen persons were killed in the State outside of New York City.

Public Health Lectures.—The annual course of free lectures for the public on the prevention of diseases, given by the Public Health Education Committee of the Medical Society of the County of New York, was begun on Tuesday, February 1. The lectures are given at the Academy of Medicine on alternate Tuesday evenings and Thursday afternoons from February 1 to March 23. The chairman of the committee is Dr. Esther L. Jefferis; the secretary, Dr. Wilhelmina A. Ragland.

The Internment of Dr. Koch.—A correspondent of *The Sun* writes that he understands the great Dr. Koch is interned in England, and he suggests that the United States request the British Government to let him come here until the end of the war. The Dr. Koch has been interned since 1910, but not

in England. There is a Dr. Koch now interned in England who is said to be one formerly held at the Norfolk Navy Yard who broke his parole and fled the country, but was caught by the English while on his way home. A case of jumping out of the frying-pan into the fire.

Convalescent Home in Switzerland.—It is reported from Berne, Switzerland, that Mrs. H. T. McCormick of Chicago has acquired property there and will establish a charitable foundation, especially a home for convalescents, which will be under the direction of well known Swiss physicians.

Hospital Boat Launched.—The *Helen C. Juilliard*, the new floating hospital of St. John's Guild, was successfully launched at Wilmington, Del., on February 5. The boat will be ready for service on July 1, and will have accommodations for 1,200 patients. The lower deck will be devoted to dining rooms, galley, and store rooms; the main deck will be furnished with benches and hammocks for the mothers and children. It will have forward a milk booth equipped with pasteurizing apparatus, ice boxes, etc., and in the after part bathrooms and storerooms. On the upper deck there will be four wards, examining rooms, an operating room, a sterilizing room, and rooms for the staff; and on the hurricane deck there will be an isolation ward and quarters for the officers and crew. When in full service the boat will have a day and night crew and a day and a night corps of doctors and nurses, and it is planned, during the hot weather, after she has returned from her regular day trip, to fill up with a fresh lot of patients and then steam up the Sound, and anchor in some cool spot until early morning.

Medical Society Elections.—The first meeting of the MEDICAL SOCIETY OF BAY RIDGE (N. Y.) was held on February 1, when the organization was completed. The officers elected were: *President*, Dr. John P. McQuillin; *Vice-President*, Dr. Robert E. Coughlin; *Secretary*, Dr. Frank E. A. Stoney; *Treasurer*, Dr. Roderick Byington. The society has for its object the promotion of sociability among its members, study, and general welfare. The district embraces that part of the Borough of Brooklyn reaching from the Narrows to Thirty-ninth Street and Gravesend Avenue.

NASHUA (N. H.) MEDICAL ASSOCIATION: Annual meeting on January 13. Officers elected: *President*, Dr. Timothy F. Rock; *Vice-Presidents*, Dr. H. H. Jewell and Dr. S. G. Davis; *Treasurer*, Dr. Albert F. Mulvanity; *Secretary*, Dr. Charles H. Babbitt.

DOUGLAS COUNTY (KAN.) MEDICAL SOCIETY: Annual meeting at Lawrence on January 11. Officers elected: *President*, Dr. E. James Blair, Lawrence; *Vice-President*, Dr. Edmond R. Keith, Lawrence; *Secretary*, Dr. Carl Phillips, Lawrence; *Treasurer*, Dr. McConnell.

DODGE COUNTY (NEB.) MEDICAL SOCIETY: Annual meeting at Fremont on January 6. Officers elected: *President*, Dr. Rupert A. Davies, Arlington; *Vice-President*, Dr. G. A. Rathbun, Fremont; *Secretary-Treasurer*, Dr. Sylvester A. Preston, Fremont.

PHILADELPHIA MEDICAL CLUB: At the annual meeting, held on January 21, the following officers were elected for the ensuing year: *President*, Dr. Judson Daland; *First Vice-President*, Dr. William Duffield Robinson; *Second Vice-President*, Dr. J. Torrance Rugh; *Secretary*, Dr. William S. Wray; *Treasurer*, Dr. Lewis H. Adler, Jr.

BUTTS COUNTY (GA.) MEDICAL SOCIETY: Annual

meeting at Jackson on January 14. Officers elected: *President*, Dr. J. Lee Byron, Jackson; *Vice-President*, Dr. B. F. Akin, Jenkinsburg; *Secretary-Treasurer*, Dr. W. H. Steele, Jackson.

GRAND FORKS DISTRICT (N. D.) MEDICAL SOCIETY: Annual meeting at Grand Forks on January 14. Officers elected: *President*, Dean Harley E. French; *Vice-President*, Dr. Thomas Mulligan; *Secretary*, Dr. H. G. Woutat; *Treasurer*, Dr. C. S. Marsden.

HATHERLY MEDICAL SOCIETY: The tenth anniversary of this society was celebrated at a meeting held in Abington (Mass.) on January 13, when the following officers were elected: *President*, Dr. C. E. Knight, Rockland; *Vice-President*, Dr. Richard B. Rand, North Abington; *Secretary-Treasurer*, Dr. Charles Hammond, Hanover.

MASSACHUSETTS SOCIETY OF EXAMINING PHYSICIANS: Annual meeting at Boston on January 26, when the following officers were elected: *President*, Dr. Francis W. Anthony, Haverhill; *Vice-Presidents*, Dr. Frederic J. Cotton, Dr. L. V. Briggs, and Dr. Timothy Leary, Boston; *Secretary*, Dr. J. H. Stevens, Boston; *Treasurer*, Dr. John S. Phelps, Boston.

MARSHALL COUNTY (IA.) MEDICAL SOCIETY: Annual meeting at Marshalltown on January 25. Officers were elected as follows: *President*, Dr. Royal F. French, Marshalltown; *Vice-President*, Dr. A. C. Conaway, Marshalltown; *Secretary-Treasurer*, Dr. G. M. Johnson, Marshalltown.

NORTHWESTERN MEDICAL SOCIETY: At the annual meeting held in Minot, N. D., on January 22, the following officers were elected: *President*, Dr. Louis Henry Kermott, Minot; *Vice-President*, Dr. Fred Ewing; *Secretary-Treasurer*, Dr. Francis A. Brugman, Minot.

WAUKESHA CITY (WIS.) MEDICAL SOCIETY: Annual meeting held at the Waukesha Springs Sanatorium on January 20. Officers elected: *President*, Dr. Byron M. Caples; *Vice-President*, Dr. Richard E. Davies; *Secretary-Treasurer*, Dr. Joseph B. Noble.

American Life Convention.—The sixth mid-year meeting of the Medical Section of the American Life Convention will be held at Birmingham, Ala., on March 1-3, with Dr. Whitfield Harral of Dallas, Tex., as chairman. An interesting program has been prepared, including a symposium on the cancer problem, participated in by Dr. F. C. Wood of New York, Mr. Frederick L. Hoffman of Newark, Dr. E. E. Tyzzer of Boston, Dr. John B. Murphy of Chicago, and Dr. H. W. Cook of Minneapolis.

Obituary Notes.—Dr. GEORGE H. M. ROWE of Boston, Mass., a graduate of Harvard University Medical School in 1868, died at his home on January 21, aged 75 years. He was a member of the American Medical Association, the Massachusetts Medical Society, the District Medical Society, and the Boston Society of Psychiatry and Neurology, and was for thirty years superintendent of the Boston City Hospital.

Dr. JOHN MALONE of Boston, a graduate of the Tufts College Medical School, Boston, in 1902, died at his home, from pneumonia, after a brief illness, on January 10, aged 48 years.

Dr. HENRY C. HACHE of Somerville, Mass., a graduate of the Kentucky School of Medicine, Louisville, in 1893, and a member of the American Medical Association, the Massachusetts Medical Society, and the Middlesex District Medical Society, died suddenly in the Massachusetts General Hospital

while undergoing a surgical operation on January 7, aged 47 years.

Dr. WILLIAM K. FLETCHER of Somerville, Mass., a graduate of the Harvard University Medical School, Boston, in 1862, and a veteran of the Civil War, died on January 13, aged 88 years.

Dr. ARATHENA B. DRAKE of Boston, a graduate of the College of Physicians and Surgeons, Boston, in 1894, and a member of the Boston Homeopathic Medical Society, the Massachusetts Homeopathic Medical Society, and the American Institute of Homeopathy, died at her home on January 21, aged 87 years.

Dr. ARCHIBALD S. HIGGINS of Manasquan, N. J., a graduate of the Bellevue Hospital Medical College, New York, in 1892, was injured in a collision between a railroad train and the automobile which he was driving, at Allenhurst, N. J., on January 27, and died a few hours later at the Ann May Memorial Hospital, Spring Lake.

Dr. EUGENE M. SMYER of Brooklyn, N. Y., a graduate of the Department of Medicine, University of Pennsylvania, Philadelphia, in 1864, and a veteran of the Civil War, died at his home on January 27, aged 74 years.

Dr. MARY A. NEUMANN of Philadelphia, a graduate of the Penn Medical University, Philadelphia, in 1881, died at her home on January 18, aged 58 years.

Dr. HANNA WHITSON LOVELL of Langhorne, Pa., a graduate of the Penn Medical University, Philadelphia, in 1865, died at her home recently, aged 80 years.

Dr. LEONARD WATERMAN of Norman, Neb., a graduate of the Department of Medicine and Surgery, University of Michigan, Ann Arbor, in 1913, died in Omaha, on January 20, aged 28 years.

Dr. CONRAD S. REYNOLDS of Kennett Square, Pa., a graduate of the Department of Medicine, University of Pennsylvania, Philadelphia, in 1883, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Chester County Medical Society, died in the German Hospital, Philadelphia, on January 22, aged 58 years.

Dr. HENRY M. JEWETT of Providence, R. I., a graduate of the College of Physicians and Surgeons, Baltimore, in 1888, died at the home of his daughter, from pneumonia, after a brief illness, on January 18, aged 55 years.

Dr. CHARLES ADNA SMITH of Texarkana, Tex., a graduate of the Rush Medical College, Chicago, in 1882, a member of the American Medical Association, the State Medical Association of Texas, and the Bowie County Medical Society, and chief surgeon at the Cotton Belt General Hospital, died at his home on January 22, aged 60 years.

Dr. JOHN AUBREY VAUGHAN of Brooklyn, N. Y., a graduate of the Eclectic Medical College of the City of New York in 1875, died at his home on January 29, aged 70 years.

Dr. CHARLES MCCREIGHT died at Philadelphia on January 22 at the age of 43 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1900. He was a member of the Philadelphia County Medical Society and of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. JOHN MULLIN BATTEN died at Downingtown, Pa., on January 23 at the age of 78 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1864.

He served as surgeon in the United States Navy during the Civil War.

Dr. JAMES A. PEEPLES died at Wrightsdale, Pa., on January 24 at the age of 74 years. He was graduated from Jefferson Medical College in the class of 1868.

Dr. ELIZA WOOD ARMITAGE died at Kennett Square, Pa., on January 28 at the age of 83 years. She was graduated from the Woman's Medical College of Pennsylvania.

Dr. JACOB KLATZKO died of heart disease at Philadelphia on January 29 at the age of 59 years.

Dr. J. B. COOK of Detroit, Mich., a graduate of the Jefferson Medical College, Philadelphia, in 1865, died at his home on February 1, aged 73 years. He was a member of the American Medical Association, the Michigan State Medical Society, and the Wayne County Medical Society, and was emeritus professor of surgery in the Detroit College of Medicine and Surgery.

Dr. THOMAS H. RUSSELL of New Haven, Conn., a graduate of Yale University Medical Department in 1875, and a member of the American Medical Association, the Connecticut State Medical Society, and the New Haven County Medical Society, died on February 2, aged 64 years.

Dr. EDWARD SMITH EVELETH of Gloucester, Mass., a graduate of the New York University Medical College, New York, in 1866, died at his home on January 24, aged 74 years. He was a member of the American Medical Association, the Massachusetts Medical Society, and the District Medical Society.

Correspondence.

IS TOBACCO A STIMULANT OR A NARCOTIC?

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I was somewhat astonished in reading Dr. Abbe's interesting article in the MEDICAL RECORD of January 29 to find him designating both tobacco and alcohol as stimulants, especially as in the course of his article he definitely points out the depressing influences of tobacco. Perhaps it is quibbling to raise the question; but it is important in doing educational work to classify influences correctly. Both alcohol and tobacco primarily have irritating and stimulating effects; but the ultimate results in both cases are markedly depressant. As the result of some extensive experimentation that I conducted some years ago, as to the effects of depressant poisons on insect life, I found that next to hydrocyanic acid gas, the fumes from burning tobacco were the most fatal to all forms of insect life. With a sufficient amount of exposure, such fumes will kill every form of life; and it should be remembered that the fumes of burning tobacco have been more or less decomposed and rendered less intensive in their effects through the heat of the burning. The fact that a narcotic blunts the sensory powers of perception and obscures pain, and thus prevents the discomfort of undertaking extra work, is no reason for classifying that effect as stimulation. Of course, the odor from a burning cigar or other tobacco, may have a stimulating effect on the nasal nerve terminals, and is hence a stimulant in the same sense that other odors and flavors may act as stimulants on the gustatory filaments. But the general effect constitutionally of tobacco is mostly depressant.

Alcohol coagulates albumin, and its first

peripheral action on individual cells may stimulate to increased activity in the cell; but as the influence penetrates more deeply into the cell, a decrease of cellular activity ensues. Of course, the molecular oxidation of alcohol also acts constitutionally stimulative at first, but the depressant effect that ensues more or less quickly overbalances the stimulating effect. The tissues in time become more or less adjusted to the influences of stimulants and narcotics, in fact, morphologically adjusted; and when that adjustment has become habitual, these narcotic and stimulating influences do not have the same effect as they do upon tissues unaccustomed to such influences.

We do not know just what the physical effect of nicotine and its burned decomposed products is upon the tissues. I have observed that in tobacco solutions, bacteria will grow to an extent that will entirely eliminate any narcotic effect in the solution. The tobacco worm grows grossly fat on the raw tobacco leaf. It has occurred to me that perhaps ptomaines may develop in tobacco due to bacterial fermentations in the curing process. There may be a splitting up of some of the protein constituents of the leaf. It is doubtful if constitutionally tobacco is as irritating as alcohol; although if it were as freely diffusible as alcohol, a general systematic primary irritation would be effected. Of course the local irritating effects of tobacco are plainly observable. So far as my observation goes, its major effect is that of decreasing functional activity in the various tissues with which it is brought into contact, and somewhat in proportion to the extent of the influence and the openness to diffusion of the tissues influenced. These effects are most quickly and prominently observed in those whose tissues are most delicate and absorptive, as in the young. The delightful sensations of a supervening narcosis are more or less realized by the tobacco habitué as well as by the consumers of alcohol, opium, or other narcotics, or by the diner who enters upon his after-dinner nap under the somniferous influence of a heavy dinner. There is a good deal to say against the tobacco habit, for esthetic, social, and economic, as well as for other reasons, although it is quite possible that in certain cases, the habitual indulgence in narcotization may prolong life through hiding from the consumer the intensity of some of the ills of existence; but there can be no question that for most individuals, the sum total of life's activities and probably the extension of life are shortened indirectly through the weakening effect of the habit.

EAST ORANGE, N. J.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CENTRAL MEDICAL WAR COMMITTEE—SUPPLY TO THE ARMY AND THE PUBLIC—VICTIMS OF THE WAR—NOTES.

LONDON, Jan. 15, 1916.

THE Central Medical War Committee has been calling the attention of local medical war committees to the duty of respecting as far as possible civilian interests in their search for medical officers for the military service. The committee has been requested to organize the profession in such a way as will enable the government to utilize the services of all practitioners fitted for the work, so as to turn their qualifications to the best purpose and deal with all

matters affecting them in connection with the present war. This throws on the committee the duty of considering in every aspect the organization of the profession for the needs of the community; since to provide the army with a regular steady supply of medical officers entails the necessity of seeing that the work of those who go to the front is carried on during their absence. Recruiting the local medical war committees should therefore be carried on with careful regard to the needs of every locality.

The Central Medical War Committee has been in conference with the National Health Insurance Commissioners and other departments responsible to Parliament for the medical treatment of various branches of the industrial population of the country and agrees with them that taking the country generally there is a sufficient supply of doctors of military age to meet any likely demand. But they are very unequally distributed, so that while some areas could well spare a considerable number, there are others in which the removal of a small proportion might bring about much inconvenience. It is then for the central committee to assist in adjusting the demands of different areas. This committee has obtained much information through the commissioners and others, but still has to look for the help of the local committees with their knowledge of local requirements.

It is rumored that the medical committee is not satisfied that the local committees have been sufficiently careful as to this, and it is known that in some cases difficulties have been brought about in regard to the attendance needed by the local populations. The local committees ought to be in possession of information as to the conditions throughout their districts, but they do not seem to have informed the central committee nor yet to have taken any action themselves. The conference advises that when a committee finds any weak district it should at once warn the Central Medical Committee that commissions should not be given to practitioners in such districts without further consideration and that it should increase its pressure on men of military age in other districts which may be able to spare some of their doctors. The Committee should be closely in touch with the panel committees in its area and the insurance secretaries and representatives of local war committees, as well as with any bodies employing a considerable number of medical men, *e.g.*, hospitals, dispensaries, or other institutions.

The Central Committee will, on its side, make use of all information coming through local committees, taking care at the same time that its activities shall in no way hinder the supply of medical officers to the army. Every local committee should take care to meet the demands made upon it, with due regard to the needs and capabilities of its own area and careful study of what other parts of the country may be doing. The War Office is leaving the organization of the profession for military purposes to a purely professional committee—a compliment to its organizing capacity and public spirit. No one has any doubt that the confidence thus shown will be fully justified.

Many persons anticipate that there will be so great a demand for medical officers in the army and navy that the general public may be inconvenienced by the withdrawal from civil practice of a considerable number of their advisers. The apprehension is not altogether unnatural, though we are more accustomed to hear complaints of the

excessive number of doctors in numerous localities. Many could easily leave their practices for a few months without loss—for example, the practitioners at spas and other health resorts frequented only during their seasons. Then there are many young men, recently qualified, who are taking various temporary offices or helping their seniors for a time in order to see a variety of practice before settling down. In one district the doctors who have gone on war service have drawn up a list of their appointments and patients in order that their work may be carried on by their neighbors during their absence, differences of opinion that may arise to be decided by the Medical War Committee. It seems to be thought that towns will find a considerable proportion of their advisers volunteer for temporary war service. But I think the probability of the public being inconvenienced is a good deal exaggerated, particularly considering the many places from which complaints of over-competition in practice are poured forth.

In the House of Commons questions have been asked as to whether advanced students might be employed or were employed, so as to save engaging more qualified men. It was replied that those who had nearly completed their curriculum would be better advised to obtain their qualifications and those less advanced should join the combatant forces if they desired to save the Crown. It was not to their advantage to become orderlies. It was not now the practice to give first commissions to candidates who had not served in the ranks. Previous service in the Officers' Training Corps gave a person valuable experience which those who had not had such service could not possess.

Among the victims of the war are: Major A. Kellas, R.A.M.C., Oct. 31; Lieut. Maurice Mackenzie, son of the late Sir S. Mackenzie; Capt. F. Shingleton Smith, son of the Clifton consulting physician; Lieut. John Cunningham Bell, Oct. 39; Lieut.-Col. Aitken Ross, son of the colonel of the Leicestershire Regiment; Lieut. Francis Joseph Wiseley, formerly assistant medical officer of the Worcester County Asylum; Lieut.-Col. L. F. Childe, formerly principal of Grant Medical College, Bombay.

The annual entertainment at the Chelsea Hospital for Women was again given on New Year's Day. Special facilities for the treatment of female relatives of soldiers are the feature of this institution. Last year 877 patients were admitted and many operations were performed. The rate of mortality was a little under 1½ per cent. The convalescent home in connection with it at St. Leonard's-on-Sea renders valuable aid in restoring to health those who have undergone treatment in the hospital.

On Saturday 2200 of the poorest children of Poplar were entertained at the Sixteenth Children's New Year's Carnival.

Between 300 and 400 orphan children of sailors and marines who lost their lives in the war were entertained on Saturday at Chatham to a tea, followed by a concert. A Christmas tree was the center of distribution of fancy and useful articles of clothing and other presents.

Emetine in Pyorrhea Alveolaris.—As a result of a series of experiments conducted by officers of the U. S. Public Health Service, it is asserted that emetine is an amebicide, but alone will not cure pyorrhea alveolaris, and that it is necessary to resort to the operative measure of scraping the roots of the affected teeth even though emetine is freely given.

4. Progress in Pediatrics. John Lovett Morse.

1. Orthopedic Work in a War Hospital.—Robert B. Osgood gives a description of orthopedic work in a war hospital based on three months' experience at the American Ambulance in Paris as orthopedic surgeon with the Harvard Medical School Unit. This experience leads him to believe that the essentials for efficient orthopedic work in a war hospital are a person interested in orthopedic surgery and with a knowledge of those mechanical principles which have to do with the fixation of inflamed joints and broken bones, and also with the restoration of function in stiffened joints and the obtaining of proper final alignment in fractures, proper material with which the work may be done, and time and assistants to use them. At the American Ambulance all these necessary conditions are fulfilled. During the months of April, May, and June, about 450 cases were under the observation of the Harvard Unit and of these between 20 and 25 per cent. presented some problem for the solution of which the help of the orthopedic surgeon was sought. The house surgeons were constantly on watch for contracting tendons and muscles and for joints which were in danger of becoming ankylosed. By this attention much after treatment and deformity was undoubtedly spared. The author describes the treatment in the following six groups of cases: 1. Simple fractures of the shafts of bones. 2. Compound fractures of the shafts of long bones, needing as perfect fixation as possible which would at the same time allow painless copious dressing or constant drainage. 3. Injuries to joints, either from penetrating wounds, fractures into them, or external trauma. 4. Ankylosis of joints complete or partial, following immobilization or secondary inflammation. 5. Contraction of tendons or muscles from faulty position or cicatrization. 6. Nerve lesions resulting in paralysis and requiring apparatus. Numerous illustrations show the varieties of apparatus that have proved most useful in treating these different types of injuries. In closing the author confesses to some doubt at the beginning as to whether an orthopedic service at a war hospital would prove interesting to the orthopedic surgeon or be useful to the other departments of the hospital. The doubt as to the interest of the orthopedic surgeon disappeared at once and work assigned to the orthopedic surgeon answered the other question.

2. Some Anthropological Comments upon the So-called "Herbivorous" and "Carnivorous" Types of Man.—E. A. Hooton calls attention to the numerous articles that have appeared within the last year on physical types of men and the relation of these types to disease, eugenics, civilization, and what not. He says that in order to establish an anthropological type it is necessary to combine the results of extensive morphological observations with measurements on long series of subjects. The evidence of the existence of such a type must then be presented in concrete statistical form, and if possible a mathematical correlation between the associated characters demonstrated. He then produces evidence of such nature that he cannot believe in the existence of the "carnivorous" and "herbivorous" types of man. He shows that there is no constant relation between bodily fullness and stature. While the attempt to bring anthropology and medical science in a working partnership is laudable, the theory of "herbivorous"

and "carnivorous" types of man falls to the ground because it is based largely on incorrect anthropological assumptions. If students preparing for a medical course were thoroughly grounded in physical anthropology and zoology it would very greatly enlarge their field of vision in their professional career and would result not only in invaluable contributions to anthropology, but would also be instrumental in advancing medical science.

9. Dr. Achilles Rose. An Appreciation. David Gilbert Yates.

1. Infantile Paralysis.—R. Tunstall Taylor emphasizes the need of greater care in the early recognition of infantile paralysis and the importance of using appropriate means to prevent its spread. Elimination of the toxin should be facilitated in every possible way. As hexamethylenamine has apparently helped some cases and can do no harm it should be given in the early stages. Rest is most important in order to give the muscles a chance and freedom from strain. Warmth helps the hyperesthesia and nerve pain. No matter whether a part is paralyzed or not, efforts at assisted active movements should be tried and passive movements and massage given, possibly aided by Faradic electricity, slowly interrupted by a pendulum to produce muscular contractures, no matter how slight. Braces must be used as light as possible, to compensate for muscular deficiency, prevent contractures, and promote a normal physiological balance. Tenotomy and myotomy must be employed later when moderate stretching will not affect the desired lengthening of overactive muscles. Tendon transplantation must be resorted to two years after the attack, based upon careful scientific and mechanical study, to produce a proper distribution and balance of power and support. Some form of tenodesis by tendon or preferably by silk can be used to supplement the tendon transplantation if the alignment is not perfect and relaxation of a joint exists. As in the writer's method, the tendon must be carried straight from the origin to the new insertion to gain the greatest mechanical efficiency, and the annular ligament must be employed when possible to take up any slack in the new order of things. The tendon is more securely fixed if sutured to a notch in the bone, retained in a fixed dressing four months, and without weight bearing for two months. Mutilating operations should be avoided as far as possible and used only as a last resort.

4. The Ductless Glands and Atypical Growth.—Seelye W. Little says that it is well known that the ductless glands have a great influence on cell growth, on inhibition of cell growth, on cell differentiation or inhibition of the same, with a consequent marked peculiarity in size, shape and development of various organs, or even of the entire individual. The same is true of the remarkably selective action on particular tissues of ductless gland influence. If there were no other evidence, the presumption would be very strong that there might be a similar connection between ductless and what are known in general as pathological "new growths." This presumption, the writer believes, becomes a conviction when one deliberately sets side by

side all the facts concerning ductless glands and all the facts concerning such new growths as cancer. He sets down in tabular form the more important significant facts and finds that no fact of either set can disprove the theory, and many offer direct proof in favor of it. Nevertheless some hitherto unknown fact may absolutely disprove what seems not to be certain. Until disproved this theory seems to the writer the most profitable and hopeful for the physician confronted with the care of a case of inoperable cancer. An argument based on the facts that ductless glands have an influence on cell reproduction, on metabolic functions, and in that matter of cell specialization, leads him to conclude that cancer development is dependent upon failure of some ductless gland or the cells depending upon it. If the theory is true, one ought to find plenty of evidence of it in a cancer patient. This, the writer believes, he finds in an accurate personal and family history of any ten cancer patients taken at random. Finally the author concludes that by exclusion, by reasoning from known facts, and by clinical trial, any case of atypical growth which cannot at present be otherwise explained or otherwise helped, should be treated by ductless gland therapy, since such treatment is by no means mere haphazard guess work. Even with the present equipment is it certain that we have a check and sometimes even a control of the growth called cancer in appropriate ductless glands thereapy?

5. Accessory Sinus Infections.—Arthur Morgan MacWhinnie recommends the following treatment with little variation in all cases of acute and chronic purulent ethmoiditis, including what some writers call sub-acute and acute purulent ethmoiditis, the one exception being the chronic hyperplastic type: Application of antipyrin, 4 per cent. solution, or adrenalin chloride with cocaine, 3 per cent. solution, to the ethmoid region, allowing the pledgets to stay in place until there is complete shrinkage; application of the author's suction pump with from 5 to 20 inches of vacuum, depending upon the susceptibility of the patient's membranes, entire cleaning of the cells, often requiring 15 inches of vacuum; injections directly into the ethmoidal cells, by means of a very fine pipette, of 50 per cent. solution argyrol. This pipette holds about 2 c.c. The patient is instructed to keep this in the nose for one hour before blowing it out. In the vast majority of sinus cases, when it is expelled, large plugs of mucus come with it, and these are frequently not replaced. This procedure is carried out every day, or on alternate days, depending upon the amount of reaction, six to twelve treatments usually sufficing. The writer has used this method for a period of over two years with marked success. He also describes his suction pump, which is illustrated by diagram.

2. The Carbohydrate Factor in the Causation and Treatment of Hyperacidity and Ulcer.—Willard J. Stone mentions certain observations relative to the dietetic and medical management founded on the following: 1. The great increase per capita of sugar during the past fifty years. 2. The possible relationship existing between this increase of sugar consumption and the apparent increased incidence of gastric and duodenal ulcer. 3. The influence of restricted carbohydrate diet in the treatment of uncomplicated hyperacidity and on ulcer. This excludes those in whom some remote pathological condition may exert reflex influence on the gastric secretion. Hyperacidity has in probably every case been a factor of at least contributory importance in the pathological changes leading to ulcer formation in the stomach and duodenum. In his experience, reflex causes in the abdomen have served as an explanation for the hypersecretion in at least 50 per cent. of the cases; in the remainder a faulty dietary with an excess of carbohydrates has been a factor. At least this much may be said: A majority of such patients are relieved of many of their symptoms by restricting their carbohydrate intake. When the hyperacidity and hypersecretion have existed for a considerable period of time with periodic intervals of improvement and relapse, definite ulcer should be suspected. A large majority of ulcer cases are amenable to medical treatment. About 25 per cent., however, become chronic and are given greater relief by surgical intervention. Patients with hyperacidity and ulcer do better with an almost starch and sugar free diet, at least during the time of active symptoms. The essential point the writer wishes to bring out is that organic acid decomposition of sugars and starches appears to play an important rôle in the production of hyperchlorhydria and its sequelæ.

3. The Epidemic of Typhus Exanthematicus in the Balkans and in the Prison Camps of Europe.—Bert W. Caldwell says that the epidemic of this disease which spread over Serbia from December, 1914, to the end of July, 1915, was, in proportion to the territory involved and the population affected, the most severe that Europe has ever experienced. Conservatively, one out of every five of the 2,500,000 population was attacked by typhus, and 135,000, including 30,000 Austrian prisoners, died of typhus during this epidemic. The hospital mortality ranged from 19 to 65 per cent. The lesson which this epidemic teaches is particularly valuable to the sanitary world, especially to those localities which are from time to time subject to an epidemic of typhus fever. It demonstrates beyond any question of a doubt that the disease can be kept out of a country by instituting proper quarantine and sanitary measures, and by the proper observance of personal and community cleanliness and hygiene. It has demonstrated with equal certainty that if it should at any time secure a foothold in any locality, it can be easily limited and eradicated in a short time. With our present knowledge of the measures which control this disease, we can take a very optimistic view of the future, and assert with confidence that the epidemic of typhus which Serbia has so recently experienced is probably the last one which will occur in Europe, unless conditions favoring an epidemic are worse than have ever before existed in the history of the continent.

7. Diagnostic Methods and Pathological Constants in Idiopathic Epilepsy.—Charles A. L. Reed presents his second report on this subject. The clinical phenomena which he has recorded, the pathological constants which he has presented, considered in connection with the now demonstrated organism, especially in the absence of facts of contrary significance, seem to justify

tentative conclusions as follows: 1. Idiopathic or essential epilepsy is an infection. 2. The infecting organism, whatever may be its primary habitat, finds its way under circumstances of forced absorption from the alimentary canal into the blood. 3. The conditions that enforce absorption from the alimentary canal consist in mechanical distortions with resulting constipation in the form of either obvious or masked stasis. 4. These conditions point to a logical line of treatment as follows: (a) The organism should be isolated in each case with reference to the development of an antigen and the possible immunization of the patient. (b) In the absence of such immunization or in recurrence after apparent immunization, but in certain otherwise favorable cases, the mechanical conditions of the intestines responsible for the enforced absorption should be surgically corrected and a stop thus put to the farther intake of the organisms by restoring the normal drainage of the bowel. (c) Postoperative treatment should be instituted to neutralize and eliminate the residual infection already established in the glands and blood of the patient. (d) In this connection it is of the highest importance to insist that the intercurrent chronic acidosis, which exists without exception in these cases, shall be as nearly as possible reversed as can sometimes be done, although only temporarily, by appropriate treatment preliminary to surgical interference. Failure to observe this precaution will result in a high surgical mortality.

8. **Skull Fractures.**—Frederic A. Besley gives an analysis of 1,000 cases at the Cook County Hospital with a report of 74 cases examined at necropsy. A careful study of 74 cases of fracture of the skull at necropsy has convinced him that the fractures of the base are not produced by a bursting force, but are due to a direct inbending force applied through the articulation of the condyles and atlas. In this series of 1,000 cases, the escape of blood and spinal fluid from the ears occurred in 316, or 31.5 per cent. of the cases. Free bleeding from the orbital cavity occurred in 10 cases. Unmixed cerebrospinal fluid from the ears occurred in 21 cases, or 2 per cent. Free bleeding occurred from the mouth and nose in 172 cases, from the nose in 118 cases, and from the mouth alone in 53 cases, or a total of 343. It was interesting to note how infrequently the pulse rate remained slow. The average pulse rate was higher in the fatal cases. In the fatal cases of all types the respiration average was consistently higher. The eye protruded in 9 cases. The patellar reflexes were increased in 67 cases, and absent in 50, with no change recorded in the rest. A Babinski reflex was observed in 55 cases, and a Kernig sign in 8 cases. General convulsions were noted in 32 cases. Clonic convulsions of the arm occurred in 6 cases, of the leg in 2 cases, and of the face in 7 cases. Rigidity of the legs was observed in 29 cases and of the neck in 29 cases. Complete muscular paralysis was observed in the muscles of the face in 47 cases, in the muscles of the legs in 55 cases, and in muscles of the arms in 58 cases. In this series of 1,000 cases, vomiting was a common symptom, and occurred in 361, or 36 per cent. of all cases. In 11 cases the vomitus was almost wholly blood.

9. **A Case of Fatal Diabetic Coma without Diacetic or Beta-Oxybutyric Acid.**—G. W. McCaskey believes this report of a case seems of sufficient interest to be placed on record because of the general tendency to trust to the Gerhardt reaction as a sign of impending coma in cases of diabetes. In the case reported the ammonia excretion was not estimated. The clinical picture was unmistakably that of the "alcoholic type" of diabetic coma. That it was really a coma from some type of

acidosis was indicated by the transient improvement following the intravenous injection of large quantities of sodium bicarbonate. The principal clinical interest attaches to the absence of Gerhardt's reaction, showing that this cannot be relied on to exclude impending coma; neither can the low blood pressure which Ehrmann says is a nearly constant feature of the precoma state be depended upon. In this case the systolic pressure was 120, falling to 75 only when coma had actually supervened. Considerable scientific interest, however, attaches to the absence of beta-oxybutyric acid, as well as the absence of the intermediary body, acetic acid, and the presence of large quantities of acetone.

10. **An Unusual Case of Appendicitis.**—Warren G. Young says that every case of appendicitis is of some clinical interest to surgeon and physician alike; but some cases stand out on account either of the operative findings or of the complications which follow. It is to the latter class that the case he reports belongs, and it is of particular interest because it terminated in recovery. The gangrenous appendix in this case was clearly due to a constriction by a Jackson's membrane. The technical difficulties encountered in its removal were due to its posterior situation and to its being buried beneath a pericolic membrane, plus an adherent cecum. The early drainage of the peritoneal cavity, which was done thirty hours after the primary operation when the abdomen was reopened on the advent of a general peritonitis, was probably responsible for the favorable outcome. There was a retrocecal abscess which was located and evacuated under local anesthesia. This was followed by pleural involvement, the infection of the liver, prompt and radical treatment of the empyema, and drainage of the abscessed liver through the transpleural-thoracic route.

2. **Factors Responsible for Gaseous Gangrene.**—Kenneth Taylor describes his experiments upon the products of the bacillus which are responsible for the pathological changes in the clinical infections and in the experimental laboratory animals and concludes as follows: 1. The gas produced by the *B. aerogenes capsulatus* is of little or no importance as a toxic factor. 2. The mechanical action of the pressure produced is usually, if not always, the most important part of the infection. To it may be charged the development of highly pathogenic possibilities in a usually rather innocent infection. It brings about (a) the death of the tissues from the resulting anæmia produced by a pressure much higher than that of the circulating blood; (b) the actual mechanical fragmentation of the tissues, especially muscle; and (c) the mechanical scattering of the infection. 3. One of the chief problems in the treatment of the infection is that of establishing drainage for the escape of the gas before the pressure has resulted in the death of the tissue.

3. **Two Cases of Heart-Block.**—Christen Lundsgaard reports a case of paroxysmal auricular fibrillation and of paroxysmal intermittent heart-block in a man fifty-nine years of age suffering from aneurysm of the aorta. A transitory attack of irregular pulse was observed, appearing at one time to be an intermittent

heart-block; at another time an arrhythmia pertetua. He also reports a case of acute heart-block in a patient suffering from rheumatic fever. In this patient an intermittent heart was observed which disappeared the same day as the joint symptoms ceased and the temperature fell to normal. He thinks there is reason to believe that the acute heart-block in infectious diseases is due to direct infectious or toxic lesions of the auriculo-ventricular bundle. In rheumatic fever such a localized myocarditis may be associated with endocarditis. In most of these cases of heart-block occurring in infectious diseases the intermittent type is predominant, a total heart-block or 2:1 rhythm having been observed only a few times.

4. **The Bactericidal Action of Normal and Infected Sera upon Different Microbes.**—K. Sakagami, working under the direction of Sir Almroth E. Wright, in the Inoculation Department of St. Mary's Hospital, states that it was already known to our scientific predecessors what microbes would grow in normal serum and what would fail to do so but still they could not get definite results. He has been working at this problem, his idea being as follows: Microbes do not as a rule grow in normal serum; if they grow the serum has no bactericidal power, and we must use another power of the serum to kill them. A way must be contrived to make such serum bactericidal by adding to it some further power. The author classifies the conflicting opinions on this subject and describes his experiments from which he finds that the *Staphylococcus pyogenes*, pneumococcus, pseudo-tuberculosis, *Streptococcus pyogenes*, and *M. catarrhalis* grow in normal serum. Normal serum has a very small bactericidal action upon the staphylococcus during the first hour of exposure, but after many hours its power decreases. Serum heated to 60° C. has no power. Normal serum has no bactericidal power upon the streptococcus. The serum of tuberculous patients has smaller bactericidal power than normal serum upon the staphylococcus and streptococcus. Serum of those suffering from staphylococcus infections has a little stronger power than that of tuberculous patients. The serum of those suffering from tuberculosis and staphylococcal infections at the same time has more power than the serum of those suffering from tuberculosis only. The bactericidal action of the writer's own serum after he had been inoculated with cholera and typhoid mixed vaccines was noticeable on both these bacteria, but otherwise was unchanged.

6. **Radical Treatment of Rheumatoid Arthritis.**—M. J. Rowlands emphasized the importance of discovering and remedying the infective focus from which pathogenic organisms which have caused the rheumatoid arthritis have been absorbed. He considers the various foci of infection and describes his method of administering autogenic vaccines. If the pathogenic organism cannot be found elsewhere he recommends an examination of the urine since the organism is frequently found in the urine. While the dosage largely depends upon the type of case as well as on individual features of the case, the writer has a plan of beginning with a dose of five millions if the organism is a streptococcus, pneumococcus, or a diphtheroid bacillus, the dose being increased according to the reaction. The arthritic reaction is important as being the chief guide to subsequent doses employed. The writer always aims at bringing about a slight exacerbation of the joint symptoms; after this the patient usually reports marked improvement. There should be an interval of seven to ten days between injections, and when there is marked improvement this may be increased to fourteen or twenty-one days. The treatment should be continued for at least a year and should be accompanied by the usual

forms of treatment, including attention to the general condition, removal to a bracing climate, baths, massage, tonics, etc.

5. Combined Preventive Inoculation Against Typhoid and Paratyphoid Fever and Bacillary Dysentery. J. Pratt Johnson and A. J. Milne.

1. **Bacteria of Gangrenous Wounds.**—H. R. Dean and T. B. Mouat have studied a series of 18 cases of gangrenous wounds, of which three only were fatal. Included in the series were 4 cases of tetanus, 1 of which was fatal, and 4 cases of gas gangrene, 2 of which were fatal. Of the 18 cases *B. œdematis maligni* was found in 15 and *B. aerogenes capsulatus* in 13. Both of these organisms are apparently possessed of powerful enzymes. The *B. aerogenes capsulatus* is peculiarly able to attack carbohydrates and the *B. œdematis maligni* proteins. Dorset's egg medium is an excellent medium for both microorganisms. The shape, size, staining reactions, and capacity for spore formation of these bacilli are profoundly influenced by the nature of the culture medium. The *B. aerogenes capsulatus* forms spores on Dorset's egg medium and inspissated serum, but not on media in which an acid reaction is produced. *B. œdematis maligni* forms spores less readily in acid media. The presence of *B. aerogenes capsulatus* and *B. œdematis maligni* is not necessarily associated with the development of gas in the tissues. Both of these microorganisms are essentially saprophytes. They have little or no power to multiply in living tissue. In dead tissue they grow rapidly and produce poisonous substances by which the adjacent living tissue is destroyed and rendered a suitable medium for the further multiplication of these bacilli. The *B. tetani* was not found in films made from the discharge in any one of the six cases of this series in which it was present. The recognition of the *B. tetani* by purely microscopical methods is complicated by the fact that slender Gram positive rods bearing an absolutely terminal spore may occasionally be found in pure cultures of *B. œdematis maligni* and *B. aerogenes capsulatus*. Moreover, pure cultures of tetanus bacilli, especially cultures on egg medium, contain many atypical forms. If broth is inoculated with material from the wound in a case of tetanus, and incubated under anaerobic conditions, the presence of *B. tetani* can often be satisfactorily demonstrated by animal inoculation. Such a broth culture should be examined at intervals, and two or three weeks may elapse before the tetanus bacillus can be demonstrated. The discovery of this bacillus in the wounds of a patient who has not developed tetanus is obviously an indication for one or more prophylactic injections of antitetanic serum. Indeed it is probable that the three organisms under consideration have probably a common source and the conditions favorable to their growth within a wound are probably identical, hence the discovery of either of these bacilli may with advantage be followed by a prophylactic injection of antitetanic serum.

2. **Acute Toxemia Secondary to Gas Gangrene.**—John Fraser and H. J. Bates have made a report on this subject to the Medical Research Committee in which they state they have observed that men suffering from an infection of their wounds by a gas producing organism frequently succumb to what appears to be an

intense and progressive toxemia which they find extremely difficult to treat. Following Professor Lorrain Smith's suggestion they are now using intravenous injection of a solution containing 0.5 per cent. hypochlorous acid (eusol) to which is added 8 grams of sodium chloride per litre and the results obtained most thoroughly justify the adoption of this method. They report cases presenting apparently the same condition, some of which were treated by this method while in others it was not used. In the cases in which these injections were given the improvement was prompt and striking, and the patients went on to recovery. The injection was made by means of a Record syringe into the median basilic vein. In two of the cases 40 c.c. of the solution were injected and in a third 70 c.c. This latter case showed that in some instances the larger dose might be given with advantage.

4. Chloramine in the Treatment of Wounds of the Mouth and Jaws.—A. R. Fisher says that the septic character of all gunshot wounds involving the mouth and the disadvantages attending the use of the common antiseptics led him to try chloramine (toluene sodium sulphochloramide) in seven cases, five being compound fractures of the jaw and two flesh wounds involving the mouth. A two per cent. aqueous solution of this agent was used for irrigation, which was carried out every hour during the day and as often as possible during the night. Chloramine besides being a powerful antiseptic has the property of penetrating the tissues, and is not so readily neutralized by albuminous discharges as the simpler chemical antiseptics. It is bland and non-irritant. While the number of cases treated was small the results were most encouraging.

5. Combined Preventive Inoculation against Typhoid and Paratyphoid Fever and Bacillary Dysentery.—J. Pratt Johnson and A. J. Milne present a preliminary report of their investigations into the possibility of amplifying the scope of preventive inoculation so as to afford protection not only against typhoid and paratyphoid fever, but also against bacillary dysentery. They use a typhoid and paratyphoid combined with sensitized dysentery vaccine, containing in 1 c.c. *B. typhosus*, *B. paratyphosus*, A, and *B. paratyphosus* B 500 million in a ratio of 2, 1, 1, plus *B. dysenteriae* (sensitized) 250 million. A dose of 1 c.c. is recommended as a first inoculation, followed after an interval of seven or eight days by a second inoculation of the same amount. It is important that the inoculations be made in subcutaneous tissue over muscle. The writers have found the pectoral region convenient. In order to secure accurate doses a 1 c.c. syringe with a moderately fine needle should be used. After one inoculation of a combined untreated vaccine specific agglutinins were found in the blood after an interval of nine to fourteen days for each of the four organisms present. Immunity was therefore rapidly produced, and it appears that the complete sensitization of the dysentery organisms not only reduces the local reaction, but produces a much more rapid and satisfactory immunization.

Berliner klinische Wochenschrift.

December 20, 1915.

Pruritus Hiemalis.—Unna regards this condition as dependent upon that state of the circulation which manifests itself in the formation of small varices, especially about the knee, calf, and ankle. The exciting causes are cold weather and exposure of the skin, as in disrobing. It is absent throughout in summer and appears with the first frost. The rationale appears to be that the venous stasis leads to oxygen hunger, this

in turn causing the itching. Another local factor is seen in the cornification of the skin which results from lack of oxygen in the stagnant blood. The winter flannels, according to this view do not cause the preventive, but actually prevents it by the resulting equable warmth. "Flannel itch" is quite a different affection. Scratching the skin causes active congestion, and as the capillary blood pressure becomes raised itching becomes intense and a burden, since it may give trouble all night. The usual effects of scratching becomes superadded to the skin, which may show thickening infection, eczema, etc. In time a chronic eczema develops. An ointment containing camphor and carbolic acid will relieve the itching, but for a cure it will be necessary to overcome mechanically the relaxation of the venules, either with elastic stockings or medicated plasters or both.

Recent Developments in Kidney Research.—Schrumpf gives a review from literature of the recent progress made in advanced studies of renal disease. A number of the contributions which he has covered have already been abstracted in this column. The distinction between nephroses and nephrites is not accepted on all sides and it is naturally very difficult to separate primary degenerative processes from inflammation and its results. It is likewise difficult to separate a purely arteriosclerotic kidney from diffuse glomerular nephritis which is so surely followed by cardiovascular lesions. It is inevitable that these viewpoints necessitate many mixed types and the pathology of the kidney can hardly be regarded as simplified by studies along these lines which are necessarily pathological, not clinical. Certain facts stand out plainly—thus experimental sublimite poisoning can produce at will a simple nephrosis. In the nephrosis type we see edema, from lack of renal permeability; a very large per cent. of albumin and formed elements; scanty and dense urine, etc. But one sees neither hematuria, high blood pressure, cardiac hypertrophy or changes in the fundus oculi. Uremia and convulsions never take place. Even the terminal shrinking of the organs does not in itself lead to death. Nephroses are practically of toxic origin, while nephritides are of bacterial origin, usually the streptococcus and pneumococcus being accused. True pregnancy kidney is a nephrosis without elevated blood pressure, but pregnant women also have nephritis with blood pressure raised. Nephritides occur in numerous clinical forms, but there is always blood in the urine of acute cases, never much albuminuria. Complete suppression of urine may occur—in fact a long parallel can be drawn between a nephrosis and a nephritis in which the symptoms of one are the reverse of those of the other. Hypertonia is a condition not the same as arteriosclerosis although it may lead to the latter. It is benign throughout. The patients have hypertrophy of the heart and a very high blood pressure. Cardiac asthma is present and valuable for diagnosis; moreover it disappears under dry diet. The second aortic sound is not always accentuated. Various evidences of cardiac insufficiency are seen, but these are not of a marked degree. Edema is almost never seen. In malignant or arteriosclerotic hypertonia the urine may appear quite normal, while albuminuria may be absent. Symptoms of N-retention are seldom seen, but many vascular phenomena are in evidence as apoplexy, vascular spasms, vascular crises, etc.

Pneumoperitonitis.—Doerfler describes a condition barely known in text book literature in which a post-

operative peritonitis is complicated by the presence of gas, either generated *in loco* or else escaped through an intact intestinal wall. The condition bears a close resemblance clinically to acute septic peritonitis with total intestinal paresis. Pneumoperitonitis may be best understood through an actual case, such as the following: the author had operated on a middle aged man for irreducible omental scrotal hernia. The omental stump was replaced in the abdominal cavity, and the herniotomy wound had healed by first intention. The asepsis seemed complete. Nevertheless colic fever and meteorism developed almost from the outset, all, however, in mild degree, the general condition being uninfluenced. There was no vomiting and gas escaped after a glycerine enemata. Not until the sixth day, or thereafter, did the symptoms seem cumulative. Meteorism had now become pathological, and tenderness was no longer localized. The tongue began to dry and the hot air chest and physostigmine were used to combat the meteorism. The latter, however, became more and more pronounced, in the absence of obstruction of the intestine. Castor oil caused stools but no lessening of meteorism. The stomach was siphoned out with the same negative result. Cyanosis and intermittence of the heart contrasted with the fairly good general condition. The author was still unable to think of anything but paralyzed intestines, and proceeded to institute a colonic fistula. As he divided the parietal peritoneum a strong hissing sound was heard and the meteorism subsided, to the great relief of the patient. It was certain that the intestine had not been wounded. Inspection showed that there was no distention of the coils, but instead a collapse. The external wound was closed and the patient at once improved. Within two days, however, the former status began to reappear, and diarrhea became a prominent symptom. Paracentesis abdominis was performed a number of times without wounding the intestine, and the gush of air was strong enough to extinguish a match. The first step toward establishment of an intestinal fistula was performed, as an emergency measure. The opening into the peritoneal cavity was prevented from closing by a tampon. During the next two weeks the patient steadily failed. The autopsy showed that the upper and lower halves of the peritoneal cavity were isolated from each other by adhesions between the omentum and intestine and the abdominal wall. The lower half showed no abnormalities, but in the upper space suppuration had occurred, and an ordinary purulent peritonitis was present. How explain the phenomenon of pneumoperitoneum? Beyond expressing his belief that a gas forming bacillus was responsible in some way, the author has nothing to offer in answer to this question. A similar case reported by Malcolm, an American surgeon, ended in recovery, apparently because of sufficient drainage. The subacute course of the case was naturally misleading, as no urgent indication for radical procedure was forthcoming. For the failure of asepsis the author blames the catgut used.

Functional Nervous Disturbances in Soldiers, etc.—

Meyer states that military experiences quite notably give rise to psychoneurotic disturbances of psychogenic origin, especially in predisposed individuals. Aside from individual predisposition it would indeed be a miracle if the persistent, almost superhuman efforts, the privations and somatic injuries could affect the highly organized, civilized creature and not leave him

without some traces of the ordeal. The results naturally are similar in kind to the traumatic neuroses in civil practice; indeed many of the army cases would be adjudged as simple traumatic neurosis. A subject of active interest in this connection is the relationship between progress and deterioration, which in turn leads to the supposition that warriors may hand down their nerve wreckage to posterity. But such a result would surely have its compensations.

Systolic Functional Heart Sounds.—According to Treupel these have a most varied origin, which may be intra- or extracardial (cardiopulmonic murmurs). They are often spoken of as accidental murmurs. Most commonly they are due to acceleration of the velocity of the blood current, relative insufficiency of the mitral valve, and particularly current relations at the pulmonary ostium, and nervous influence upon the decline of cardiac contraction. These generalizations, however, hardly do justice to the many special problems involved in functional murmurs. Thus, let us suppose the existence of a high diaphragm. The x-ray shows us not only a broadening of the heart's shadow but a kinking at the origin of the pulmonalis. This anatomical status would account for a murmur. Certain murmurs are evidently due to dilatation. In fact Henschen regards all functional murmurs as belonging here. Dilatation results from disturbances of nutrition in the heart muscle, as seen in anemias, infections, intoxications, etc. Others, however, cannot see a dilatation component in these cases. Henschen's criterion is simple percussion, but the x-ray has shown that his diagnosis is often correct.

Experiences with Malignant Phlegmon.—Under this head Tappeiner describes two types of this affection, of which one is gas phlegmon, while the other, unnamed, is still more severe in type. Gas phlegmon may follow any kind of wound but is more often seen in deep, ragged injuries with much wreckage of soft tissues. It is correspondingly rare after clean wounds from infantry bullets. As a rule wound infection appears in about three days, exceptionally during the first twenty-four hours, and at the margins of the wound. Gas phlegmon has simulated emphysema, which must be excluded. Palpation about the wound edges will cause the sensation of crepitus. There may also be latent or delayed infection with the bacillus of gas gangrene. The general symptoms are often those of sepsis. The patient feels well, and even experiences euphoria. This mental status does not prevent a physical collapse which often demands prompt intervention. Free, deep and multiple incisions must be followed up by disinfection with hydrogen peroxide. The author has cured at least 50 cases of gas phlegmon in this manner. The other form of phlegmon is of a livid appearance. This coloration must not be confounded with erysipelas. The swelling is only medium in amount, and the tenderness but slight; the former is due to a gelatinous infiltration of the connective tissue. When, however, it occurs in a limb the latter may swell greatly, doubtless because of venous thrombosis. In contrast to the gas phlegmon, the process may begin at some distance from the injury. The radical management of this type is much the same as that for gas gangrene.

Magnesium Chloride in Wound Treatment.—Pinard states that he treats all wounds by application of an 18:1000 magnesium chloride solution. The wound is first irrigated with the solution and is then covered with a thin layer of sterile absorbent cotton wet with same. In case of profuse suppuration the dressings are changed twice a day for the first five days, then once a day.—*Bulletin de l'Académie de Médecine de Paris.*

Book Reviews.

QUANTITATIVE LAWS IN BIOLOGICAL CHEMISTRY. By SVANTE ARRHENIUS, Ph.D., M.D., LL.D., F.R.S., Nobel Laureate, Director of the Nobel Institute of Physical Chemistry. Price, 6 shillings net. London: G. Bell & Sons, Ltd., 1915.

IN 1904 Arrhenius delivered an important series of lectures, published three years later, on the application of chemistry to the study of biological antibodies. In these lectures he applied the laws of physical chemistry to certain quantitative researches, made chiefly by Madsen in the Danish Serum Institute, on the observed processes of immunity, and also analyzed a large number of similar experiments published by other investigators, showing that when observations were made with sufficient accuracy they conformed to the laws deduced by the physicochemical study of simple chemical reactions. While this monograph did not add new observations, it correlated many apparently unrelated phenomena; showed that Ehrlich's method of explaining immunity by a happy nomenclature left many questions unsettled; and laid the foundations for further investigations. Many of these points are included in the new volume just issued by this talented author, which is a re-working of the Tyndall lectures of the Royal Institute for 1914. In it fresh illustrations are given of the importance of the application of the laws of physical chemistry to biological phenomena. The rates of the reaction as observed in digestion experiments are examined and shown to follow the same law as such widely separated processes as the inversion of cane sugar, the decomposition of tetanolysin, and the destruction of hydrogen peroxide by colloidal platinum. The influence of temperature on the inversion of cane sugar, on the saponification of cottonseed oil, and on the coagulation of milk is also shown to be similar in all these widely different processes. It is interesting to note that the killing of bacteria by disinfectants, their destruction by hot water, and the hemolysis of red cells, all follow the same physical laws. As immediately practical these studies can not for one moment be considered, but they point the way to further research which may add much to medicine. Until we can apply quantitative methods to these complex biological phenomena, we can know but little; and Arrhenius and his pupils have done much to clear up some phases of an extremely vague and difficult subject, about which much has been published, but in which much still needs clarification.

A MECHANISTIC VIEW OF WAR AND PEACE. By GEORGE W. CRILE. Edited by Amy F. Rowland. Price, \$1.25. New York: The Macmillan Company, 1915.

THIS volume presents the substance of a lecture delivered at the Western Reserve University and constitutes an application of the principles enunciated by the author in his work "The Theory of the Emotions" to conditions observed while in the war zone. To those familiar with the larger work it is unnecessary to go further. Crile sees in war an intense activation of the kinetic system of all the inhabitants of the warring nations, an activation which made necessary a release of muscular activity of one sort or another. He speaks of the comparative anesthesia accompanying a state of exhaustion and cites numerous interesting instances. He attempts to show that the "action-patterns" of war are established in our minds from the earliest moment and that therefore it is highly improbable that war will ever become a thing of the past. Nevertheless if this result is ever reached it will be because education has been exploited as efficiently as war and a civilization built up "freed to some extent from its menacing phylogeny." It is a most interesting philosophical discussion, though we rather doubt the possibility of its practical application.

INDIVIDUALITY IN ORGANISMS. By CHARLES MANNING CHILD, of the Department of Zoölogy, the University of Chicago. Price, \$1.25 net. Chicago: The University of Chicago Press, 1915.

THIS book supplements and completes the author's presentation of his system of biology contained in his work "Senescence and Rejuvenescence," which was reviewed in a previous issue of the MEDICAL RECORD. In size and weight it is in pleasing contrast with its ponderous predecessor. In matter it is an expansion of Chapter IX of the larger work, and the style is the same. The present volume can hardly be regarded as an independ-

ent work, for in order to understand its contents one must have read the other.

The problem discussed is the nature of that unity which we call an organic individual. The point of view is physiological. The organism is regarded as a reaction system consisting of certain physico-chemical activities in a specific protoplasmic substratum. Differentiation is due to differences in strength of stimuli received at different levels from the region of greatest metabolic activity,—the apex of the stem in plants, the head in worms, the brain in higher animals. It is a dynamic, as contrasted with a morphological, conception of the individual.

The problem is stated and the proposed solution outlined in the first three chapters. The evidence drawn from experiments on regeneration in various lower animals and plants, occupies two chapters, and is the most interesting part of the book, which closes with an interesting chapter on the relations of the author's views to problems of reproduction and heredity.

As pointed out by the author, the problems of reproduction, differentiation, and heredity have been attacked chiefly by morphologists from the point of view of structure. The value of the present work lies in the light it throws on these problems from another angle. The explanation offered, based as it is upon a long series of carefully conducted experiments, is attractive in its simplicity. But it remains to be proved that it is adequate to explain the extremely complex phenomena in question.

AMNESIA AND ANALGESIA IN PARTURITION (Twilight Sleep). By ALFRED M. HELLMAN, B.A., M.D., F.A.C.S., Adjunct Attending Gynecologist and Obstetrician Lebanon Hospital, Attending Gynecologist German Hospital Dispensary, Fellow New York Academy of Medicine, etc. Price, \$1.50. New York: Paul B. Hoeber, 1915.

TWILIGHT sleep is probably more widely discussed among the laity to-day, than any other medical subject. For this very reason every physician is constantly being asked his opinion as to its value. Unfortunately in many instances he is unable to give an intelligent unbiased opinion as he has had neither the time nor the opportunity to acquaint himself thoroughly with the subject. For this reason we should welcome Dr. Hellman's book. In it he has made it possible for one with a minimum expenditure of time and effort to get a very clear idea of the nature and value of twilight sleep. Dr. Hellman briefly reviews the history of scopolamine in obstetrics, and then takes up in detail the Freiburg technique of twilight sleep. Following this he discusses the controversy between Freiburg and Berlin. The history of twilight sleep in England and America is also reviewed. The book is well written and concise and should prove valuable.

LABORATORY METHODS, with Special Reference to the Needs of the General Practitioner. By B. G. R. WILLIAMS, M.D., and E. G. C. WILLIAMS, M.D., with an Introduction by VICTOR C. VAUGHAN, M.D., LL.D. Third Edition. Price, \$2.50. St. Louis: C. V. Mosby Company, 1915.

A CAREFUL perusal of this volume will cause the reader to have a good deal of sympathy for the poor general practitioner who is being so carefully looked after. The object is apparently to instruct those men who have had insufficient teaching in their medical course, and several of the methods advised are curiously ill-adapted for this purpose. The authors apparently never think of the difficulty and danger of handling sputum and bacterial smears made on cover slips, and so do not mention the use of slides, which is much more convenient. The bacteriological section is quite inadequate in conception as well as treatment. Can one imagine doing any bacteriology with a basin of 1:1000 bichloride at one's elbow, in which one's hand are to be immersed every little while? Speaking of the gonococcus, they say "it is not necessary to use Gram's stain in order to avoid confusion with other micrococci," surely a very dangerous teaching. Blood smears, paradoxically, are directed to be made on slides. They prefer the diazo test to the Widal in the diagnosis of typhoid fever. It would take much too long a time to mention all the points in which the authors differ from the reviewer. Certainly it is not a safe or valuable volume to hand to the untrained "general practitioner," without a warning as to its limitations, while a laboratory man of any experience would have little use for it.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 27, 1915

THE PRESIDENT, DR. HOWARD LILIENTHAL, IN THE CHAIR.

Bronchiectasis from the Standpoint of the Bronchoscopist.—Dr. SIDNEY YANKAUER presented this paper in which he stated that the bronchoscope had been used for over a decade for the removal of foreign bodies, but up to the present time had not been employed for the endobronchial diagnosis of chest diseases. This was largely because bronchoscopy was more difficult than other endoscopic procedures, because respiration must proceed uninterruptedly through the bronchoscope itself during the entire examination. The extreme sensitiveness of the mucous membrane stimulated deep breathing and the respiratory movements caused a continual displacement of the field of vision. Coughing and expectoration of mucus obscured the illumination and interfered with the observer's vision. With the perfection of the instrumentarium these difficulties had been sufficiently overcome for the purpose of removing foreign bodies. For the purpose of endobronchial diagnosis, however, the bronchoscopist must have matured his experience to such a degree that the introduction of the bronchoscope, the recognition of the tracheal bifurcation, the entrance into the right or left bronchus at will, and the identification of the openings of the individual secondary branches leading to each of the five lobes of the lungs had become matters of elementary simplicity. The endobronchial diagnostician must observe the size, and shape of the trachea, the main bronchi and the secondary and tertiary branches as far as he could see; he must observe the color and texture of the mucous membrane in all parts of the bronchial tree; he must note the respiratory and cardiac pulsatory movements, the size, configuration, and position of the bifurcation as well as the spurs which mark the opening of the minor branches, and he must determine the amount, character, and source of any secretion that might be present. A suction apparatus had been used for some time for the removal of secretions. When the technique of its employment was understood it was a valuable aid in diagnosis. The bronchoscopist must also be skilled in the use of forceps for the removal of specimens for microscopical examination. Specimens should never be taken from the spurs at the openings of the branches, since at this point the mediastinal tissue came close to the surface. Specimens should be removed only from the lateral walls. In the majority of patients suffering from bronchiectasis or lung abscesses, bronchoscopy was well tolerated. In tolerant individuals it could be performed under local anesthesia; in those less tolerant, under local anesthesia after the previous hypodermic use of morphine, with or without scopolamin. In patients who were not tolerant or those with short thick necks general anesthesia was advisable. The writer considered the endobronchial diagnosis of bronchiectasis under the following heads: (1) Foreign bodies, (2) benign tumors, (3) malignant growths, (4) syphilis and tuberculosis, (5) differentiation between various forms of the disease itself. The cases in which foreign bodies had remained in the bronchus for a long time corresponded in their clinical course and physical signs exactly with the cases generally diagnosed as bronchiectasis, with the exception that the history of the inhalation of a foreign body was definitely given as the cause of the cough. However, a number of cases might be cited in which such a history could not be obtained and yet in which a foreign body was discovered to have been the cause of the trouble. Furthermore, the radiograph did not always show the presence of a foreign body even when one was known to be present. If the foreign body happened to be one transparent to the rays the picture obtained would be the same as in lung abscesses in which there was no foreign body. When a foreign body was found in a bronchiectatic cavity, its removal had resulted in a cure of the suppurative condition, whenever the foreign body had remained intact, so that it could be completely removed. Every case of bronchiectasis or lung abscess should be bronchoscoped for the purpose of locating any foreign body that might be present and no major operation was justifiable until the presence of a foreign body had been excluded by bronchoscopy. The writer had seen about nine cases of lung abscess following the removal of the tonsils un-

der general anesthesia. The exact relation between the tonsillectomy and the lung abscess was not clear and Dr. Morris Manges was making a study of it. Benign tumors might occur in any part of the bronchial tree; for instance, the writer had removed a granuloma from the lower part of the trachea, had found a stenosis of the left main bronchus caused by the pressure of an extrabronchial growth, and a stenosis of the lower part of the trachea caused by pressure upon the left side of the trachea of a pulsating tumor which was afterwards determined to be an aortic aneurism. A number of cases cited showed that a bronchoscopic examination in cases of carcinoma had revealed a change in the texture of the mucous membrane, it being darker in color and having a nodular or granular appearance. Specimens removed through the bronchoscope in these cases showed the presence of carcinoma. If bronchoscopic examination was made early there was no doubt that quite a few lung cancers could be recognized early enough to permit of successful surgery. Endobronchially three groups of cases could be distinguished. In the first of these there was dilatation of one or both of the main bronchi which could be distinctly recognized through the bronchoscope. In the other two groups the main bronchi were not likely to be dilated, but contained secretion, which even when evacuated by the suction apparatus, continued to reappear from the smaller bronchi. From the surgical standpoint it was of the utmost importance to distinguish between cases of diffuse dilatation of the larger bronchi, cases of multiple peribronchial abscesses, and cases of abscess involving only one part of the lung. It was not only necessary in such cases to recognize that pus came from a single branch only but also to identify the particular branch from which it came. The author cited cases that illustrated the accuracy with which a pulmonary lesion could be located through the bronchoscope and also the accuracy with which changes in the texture of the mucous membrane could be recognized. Considering the novelty of the endobronchial method in the diagnosis of these conditions the results thus far obtained had been most encouraging. In most instances which had come to operation or to autopsy, the endobronchial diagnosis had been confirmed. In handling these cases the writer had secured definite results by the following method which he had devised. He had constructed a double tube which was introduced into the bronchiectatic cavity through the bronchoscope; through the smaller tube normal saline was injected, while at the same time suction was applied through the larger tube. The fluid was thus removed as fast as it entered the bronchus. By directing the tube at various parts of the wall of the cavity, a thorough irrigation was accomplished. It had been possible in this way to irrigate each lung with about eight ounces of salt water at one sitting under local anesthesia. After two or three irrigations the foul odor of the secretion disappeared and the amount became markedly reduced. This beneficial effect lasted only a few days unfortunately, when the irrigation had to be repeated.

Dr. MORRIS MANGES said he could find but one fault with the paper, and that was with the title, which he believed to be misleading in not showing the worth of the paper. It was the general practitioner who must be reached if these cases were to be properly treated. The work done in bronchiectasis in clearing up this field and especially in the differentiation of this condition, the work of Drs. Yankauer, Meyer, and Lilienthal, would be defeated unless the general practitioner received proper instruction regarding bronchiectasis. Dr. Manges said he trusted that what Dr. Yankauer had brought out would be an incentive for others who were working in this field of diagnosis. Bronchiectasis was a common disease and continued year after year. The reason for the failure of its recognition was because of the lack of proper education of the general practitioner. The x-ray diagnosis was often misleading and it had been Dr. Yankauer's privilege to correct many x-ray diagnoses. By means of the bronchoscope a diagnosis of bronchiectasis should be made earlier. With regard to foreign bodies it should be an axiom in every case of bronchiectasis and in every case of pulmonary suppuration, especially if monolocular in character, that the condition should be regarded as possibly due to a foreign body. The attempts to relieve the advanced cases of bronchiectasis by washing out with argrol and other solutions showed what could be done. In regard to the frequency of abscess of the lung occurring after tonsillectomy, in one hospital nine cases came under observation within a period of four months.

Dr. WILLY MEYER said that they all recognized the value of the bronchoscope particularly when they wished to make a refined diagnosis of these conditions. Bronchiectasis was a peculiar disease. An attempted diagnosis by means of auscultation and percussion was extremely difficult and showed how little could be learned by these means. Much depended upon the history of these cases, such as clubbed fingers, etc. Efforts to localize the trouble became a task of extreme difficulty. In bronchiectasis it had been proposed to inject the bronchial tree with collargol and this was what he proposed at the International Congress of Surgeons which met in New York in 1914. But not much had been accomplished by this procedure. Dr. Meyer hoped that more good effects would be shown by the use of bismuth. It should be remembered that these patients came first into the hands of the general practitioner and, therefore, the necessity that a refined diagnosis, a distinct diagnosis, be made early, should be emphasized. These were surgical and not medical cases. Nothing but a radical operation would help these individuals.

Dr. N. W. GREEN said that bronchoscopy, although a difficult procedure, was becoming easier as the instruments used were becoming more efficient. The bronchoscope was surprisingly well tolerated by the conscious patient. It gave one the means of exact visual diagnosis, in many cases surpassing the x-ray. The x-ray should be used first in cases of long standing. The bronchoscope was an instrument of precision after an area under suspicion had been located by radiography. It was comparatively easy to pass the tube down the bronchus and into the cavity if one had a suitable aspirator with which to remove the pus. Dr. Green agreed with Dr. Yankauer that it was advisable to have cases of lung abscess or bronchiectasis examined with the bronchoscope before further surgical procedure. In many cases coming to a general surgical service the chest must be opened to let out the pus of an ampyema which was secondary to a lung abscess. This might establish a bronchial fistula. In these cases this was not a bad thing. It was a question of the pus in the cavity being emptied through the mouth in large quantities or through the side into dressings. In the bronchial fistula cases there was better drainage and the health of the patient improved while the chest remained open. After the pus had been evacuated the bronchoscope should be used to search for a foreign body. The depth of a cavity from the chest wall and the distance from the glottis might be estimated with the bronchoscope and an indication might be obtained as to the subsequent surgical procedure. Removal of the foreign body alone would not always clear up the pus. In this class of lung cavities it was well to proceed very slowly. Surgical procedures should be carried on in several stages, doing only enough at one time to complete one stage and leaving the patient with a reserve for safety. As far as was feasible it was well to do the preliminary stage under local anesthesia. Surgical treatment must first aim to reduce the size of the cavity emptying into the bronchus; later it must be more radical if the pus was to be cleared up. It might be well to let the patient pass his years under improved rather than cured conditions, since an attempt to produce absolute cure in these cases might lead to fatalities.

Dr. GEORGE MANNHEIMER said that these cases of bronchiectasis usually landed in tuberculosis institutions. There were some features which distinguished such cases from the ordinary cases of tuberculosis. The condition was usually located in the lower lobes. Dr. Mannheimer called attention to one form of treatment employed, practically placing the patient "on his head" by raising the foot of the bed. Posture in these cases was of great help. The examination of the sputum gave most valuable diagnostic aid. But if there were elastic fibers present in the sputa, but no tubercle bacilli, he said they could be reasonably sure that the case was not one of tuberculosis. Patients with bronchiectasis should not be consigned to tuberculosis hospitals. The open-air treatment for them, however, was as valuable as it was for the tuberculous patient.

Dr. HOWARD LILIENTHAL said that the importance of the use of the bronchoscope in bronchiectasis could be compared with the importance of the cystoscope in diseases of the kidney. The bronchoscope gave some kind of information regarding any disease of the bronchial tubes and lungs just as did the cystoscope in diseases of the kidney (not of the bladder). With regard to the cases of bronchiectasis following tonsillectomy, nine cases had been reported at the Mount Sinai Hospital

within a period of four months; to this number he said he could add one more case, making ten altogether, and all the patients were absolutely miserable. If they could have been operated upon early it would have been fortunate because a cure might have followed. In these cases there was a history of quinsies with final removal of the tonsils; there was the characteristic sputum, the clubbing of the fingers, and the x-ray showed a bronchiectasis of the middle lobe of the right side in one case. After operating upon this case, the patient was discharged cured at the end of two months. This was one of five cases Dr. Lilienthal had operated upon with good results. In every case he had followed, when the end came it resulted from hemorrhage. Because of the adhesions which formed he did not believe in a two-stage operation, but he believed the operation should be finished at one stage.

Dr. YANKAUER said that the solution used was the normal saline. Injections of x-ray opaque substances had been tried repeatedly. He had often used collargol but it was immediately expelled. However, if the bronchus had been irrigated before the use of collargol, more of the injected material might have remained in the bronchiectatic wall.

Some Observations on the Action of Pituitary Extract.—Dr. SAMUEL W. BANDLER read this paper. He stated that pituitary extract was supposed to have a decided effect in stimulating the contractions of the bladder and in giving force to intestinal peristalsis. He had found little need of it in the bladder cases, since its action was uncertain and in the female, catheterization was so readily carried out that the bladder could be emptied with minimum difficulty and with practically no danger of infection if urotropin was used systematically. As to the action of pituitrin on intestinal peristalsis, Dr. Bandler said he could speak with the greatest certainty and assurance. In postoperative cases, often as a routine procedure, it had a very beneficial effect in starting the intestinal activity as an aid to enemata or drugs given by mouth; repeated hypodermic injections of pituitrin often overcame symptoms simulating intestinal paresis, and as a general stimulant in post-operative cases it was of the greatest value, taking a position on a plane with caffeine, strychnine, digitalis, and camphor. The writer had used it in quite a number of cesarean section cases in small doses, repeated several times a day, for several days after the operation. It not only had an excellent effect on the uterus, but its effect on the intestinal activity could be readily recognized. In performing a cesarean section, as soon as the incision was made in the abdominal wall, a hypodermic injection of pituitary extract was given. Its effect in contracting the uterus after the extraction of the fetus and placenta was marked; there was naturally no bleeding at all from the sides of the wound, and the interior of the uterus bled only to the slightest degree. It also rendered sewing the uterus a most simple procedure. Another reason for continuing its use in cesarean section was because of its stimulating action on the secretion of the breasts. After cesarean section, Dr. Bandler said he did not limit himself to pituitrin alone but gave these and all other post-partum cases ergotole for long periods. In the third stage of labor he always used ergotole, no matter how much pituitrin might have been given before. The value of this drug during the emptying of the uterus in abortion, hydatid mole, etc., varied, but in his experience it had no marked action, at least, no rapid action, though he used it in practically every case. He used the drug every day and for many days after abortion, and after curettage for menorrhagia or metrorrhagia. An ampoule was given in one or divided doses. The effect upon the contraction of the uterus and its action upon the ovaries was sometimes quite marked, in other cases quite slow. The hypodermic use of pituitary extract was an excellent ambulatory treatment for menorrhagia or metrorrhagia in young girls, in whom examination, or treatment, or curettage were out of the question. A hypodermic might be given every day if possible for days or months. Only rarely were such patients so sensitive that the drug had to be given in small doses. A series of thirty-three cases of menorrhagia and metrorrhagia treated in this way at the Post Graduate Hospital by Dr. J. S. Boldt included cases of fibrosis uteri, fibroids of the uterus, hyperplastic endometrium, subinvolution, retroversion, vaginal fixation, salpingo-oophoritis, and posterior parametritis. The number of injections given varied from ten to thirty, one c.c. being given every other day hypodermatically. The reaction was very slight and the results were immediate. It acted much more promptly and efficiently

than any other drug available at present. The effects of the drug were not permanent; it lasted over two menstrual periods, in a few cases longer, than the symptoms tended to return. If pituitrin might not be given by needle, then the extract of the posterior lobe or of the whole gland might be given in powdered form. The whole gland in capsule might be given for long periods, with encouraging results. The whole gland was a splendid tonic in some cases of asthenia. The greatest find as regarded the physiological action of pituitrin was to be noted in the field of parturition. It had no effect in inducing labor, but once labor was on the way, whether recognized or not, the action of the drug was most remarkable. This had suggested the use of the hypodermic injection of pituitrin as a means of differentiating between true and false labor pains and thus relieving the obstetrician's doubt as to whether the patient was in labor or not. If the patient was in labor three hypodermics would produce regular, rhythmical, continued labor pains; if the patient were not in labor small pains might be produced which would stop in half an hour or so and would not recur. A field in which pituitary extract found an excellent opportunity for effectual action was in the induction of labor. If a Barnes bag was introduced into the cervix, a few hours afterwards the patient experienced a sensation of pressure and discomfort, if then pituitary extract was given in small doses and repeated, labor pains came on and labor progressed without any difficulty. In dry labor pituitary extract given shortly after the membranes ruptured had saved hours and hours of waiting. As to the indications for the use of pituitrin in labor, it might be said that when conditions were normal, and the relation between the fetal head and the pelvic bones was normal, when the presentation was normal, when all that was needed was sufficient uterine force, then one might use pituitary extract. Emphasis must be laid on the expression, all that is needed was sufficient uterine force. In labor the action of pituitary extract in primigravidae, if properly brought into force, reduced the duration to one-half, so that the average duration of labor in a primigravida could be made between seven and ten hours. After giving pituitary extract one might leave a primigravida for a while, but one might never do this with a multigravida. The head of the fetus must be well molded and fixed in and through the brim of the pelvis before pituitary extract was given by the general practitioner. But whatever the stage of the labor this rule did not hold good in women who had had one or more children, because in them the head was rarely fixed in the brim before or in the early stage of labor. Here one must be guided by the history of previous labor or labors. The important point with reference to pituitrin was that it diminished the necessity for forceps most decidedly; in fact, in his own practice it had almost abolished the use of forceps under this circumstance. Moreover, the pituitrin saved the loss of time and waste of strength incident to a prolonged labor. As soon, in the second stage, as uterine forces were no longer effective in causing the fetus to descend satisfactorily, pituitrin might be given. Pituitary extract was not contraindicated when the head lay well molded in or just past the brim, with the membranes unruptured, and the cervix refused to dilate. This condition was an indication for its use. There was no danger of rupturing the uterus so long as the membranes were intact. The action of the drug, however, lasted only a short time and it must be repeated in small doses. It was natural that a rupture of the uterus should occur with large doses of this drug where there were malrelations, malpositions, and disproportions between passage and passenger. From his personal experience Dr. Bandler said he felt that he could do with pituitrin even if more slowly, all that forceps had ever accomplished, and could do it just as faithfully and with equal certainty as to the life of the baby, and surely with greater assurance as to the conservation of the soft parts of the perineum.

Dr. JOSEPH WIENER said he wished to discuss the paper from the surgical standpoint. The field for the use of pituitrin was a large one; Dr. Bandler's field was only one of the many which called for the use of this agent. In regard to the methods of administration, there were three: by the mouth, hypodermically, and intravenously. Dr. Bandler regularly gave it in only one of the three ways, namely, hypodermically. He advised against giving it intravenously because it was a dangerous procedure. Dr. Wiener said he had never seen any bad results from the hypodermic or intramuscular injections. Used in either of these two ways in

postoperative and all abdominal operative conditions, it was of great value, especially in helping to clear up existing intestinal paresis which might in time become an intestinal obstruction. There was another advantage in the use of pituitrin in postoperative conditions in that it permitted the use of large doses of morphine after operations. He was to-day using pituitrin in large doses in every postoperative case that required morphine. Before he had begun using pituitary extract, he said, he was very loath to try it, but now he employed it in every case that called for it. Many of those who otherwise would die of exhaustion if given pituitrin and then morphine, producing a sleep of four, six or eight hours, might be saved. Dr. Wiener did not give the drug as did Dr. Bandler—in divided doses. The use of this drug aided in clearing up the differential diagnosis between pure intestinal obstruction and the border line obstruction. If ten, fifteen, or twenty minutes following the administration of pituitrin, the intestinal peristalsis increased, he knew that an intestinal obstruction was present.

Dr. ARTHUR STEIN said he believed the usefulness of pituitrin was mainly in the obstetrical field which included also the cases of abortion, and that here its use had brought about a revolution, especially in those cases of long drawn out labors which did not require forceps because the labor had not advanced far enough. Dr. Stein's experience with pituitary extract at the Harlem Hospital was very extensive in Dr. Brodhead's service and mainly in cases of cesarean section; it really acted wonderfully. Practically a bloodless operation could be performed. Dr. Bandler had sounded a warning; every practitioner who intended to use the drug must be sure of his pelvimetric findings, and note carefully whether the pelvis was normal or contracted. If unable to do this he should not resort to the use of pituitrin. One should use it in only absolutely normal cases. The danger of uterine rupture should be kept in mind when there was a disproportion between the pelvis and the oncoming child. Dr. Bandler had mentioned the use of pituitary extract for diagnostic purposes to see whether labor was going on or not, whether real or false labor pains were present or not, and he said he wished to add another type of cases, where the labor pains had ceased. The field of application of this agent in obstetrics was rather big; there was no question regarding the shortening of the time of labor; cases that might run eighteen to twenty-four hours might be shortened to ten, or twelve, or even eight hours. There was no doubt that the use of pituitrin was of great help in post-operative gynecological cases and certainly did away with catheterization; its use stimulated the muscular condition of the bladder and avoided the necessity of catheterization. This also stimulated the intestinal condition as well.

Dr. ROSS MCPHERSON said he had used pituitrin for a considerable period of time. Its employment had been suggested to him by a member of the Rockefeller Institute at a time when it was not much used. He was told that the effect upon the musculature was very marked; he had tried it and he found its action a very marked one. He had not found that it had much effect, however, in menorrhagia, but in post-operative intestinal stasis he obtained a very striking action. He always avoided the use of the catheter except in those cases where it could not be helped, in the difficult labor cases and after total hysterectomies. One or more injections of pituitrin would induce micturition without difficulty. Its use was contraindicated when there was a disproportion between the size of the pelvis and the size of the child's head. In the prevention of post-operative hemorrhage it was a very useful agent.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held December 3, 1915.

DR. JOHN DOUGLAS IN THE CHAIR.

Intrahepatic Cholelithiasis.—Dr. RICHARD LEWISOHN presented a man, thirty-one years of age, who had been admitted to the Beth Israel Hospital on November 19, 1914. He had been sick one day before admission. His most marked symptoms were pain and rigidity in the right upper abdomen. The pre-operative diagnosis was gangrenous cholecystitis and perforated duodenal ulcer. An immediate laparotomy was performed and the liver was found to be studded with small nodules.

One of these nodules at the diaphragmatic surface of the liver was incised and presented three small gall-stones. A localized peritonitis had been caused by the perforation of one of the stones at the under surface of the liver. The stones weighed between 2 and 3 mgs. Dr. Lewisohn pointed out the extreme rarity of this condition and stated that this was the first typical case of intrahepatic cholelithiasis which had been diagnosed on the operating table. All the other cases, about 150 in number, in the literature, were post-mortem findings. Dr. Lewisohn discussed the etiology of this rare disease. The patient had a biliary fistula which persisted for about eight months and then closed automatically two months ago; he was today apparently in perfect health.

Perforated Gastric Ulcer.—Dr. EDWARD W. PETERSON presented this case. The patient was a man, thirty-five years of age, with a negative family history. His alcohol and tobacco habits were in moderation. His present trouble began in 1910, when he had more or less gastric disturbance. One night, about four hours after supper, he had a very sharp attack of abdominal pain lasting about two hours and from this time on he had discomfort and vomiting in the evening, four or five hours after eating, with sour eructions, pain, etc., which were relieved by vomiting. The vomitus consisted of the supper showing but little digestion. The pain was sharp and boring but did not radiate to the back or shoulders, and was uninfluenced by any kind of food ingested. He had never had jaundice. His appetite was good. He was constipated, and he had lost 26 to 30 pounds since December, 1909. He was first seen in July, 1910. The examination of the vomitus showed red cells, leucocytes, mucus, large squamous epithelium from mouth or esophagus. The examination of the gastric contents showed free hydrochloric acid varying from 20 to 57. The total acidity was from 42 to 87. The blood count showed 2,200,000 red cells, 8,600 leucocytes, 80 per cent. polymorphonuclears, and 49 per cent. hemoglobin. The examination of the urine was negative. Examination of the heart and lungs was also negative. The abdominal reflexes were exaggerated. The muscular tone was good. There were no palpable masses. Fluoroscopic examination showed marked retention. The diagnosis was pyloric stenosis due to ulcer. Upon opening the abdomen all the organs of the upper abdomen were found to be matted together in firm adhesions; after freeing the gall-bladder, the pylorus and stomach were found to be attached to the under surface of the liver. When the stomach was freed there was found a perforated ulcer on the lesser curvature about 2½ inches from the pylorus. This perforation, about the size of a 5-cent piece, was with difficulty closed; this closure caused considerable distortion of the stomach. As the pyloric obstruction was relieved upon release of the adhesions, a gastroenterostomy was not considered necessary. The patient made a prompt recovery and was free from digestive disturbances for about two months. He gained 15 pounds in weight. Then his symptoms recurred and were practically the same as before the operation. In May, 1911, he re-entered the hospital and a secondary operation was performed. Adhesions to the gall-bladder, stomach and liver, etc., had reformed. No attempt was made to separate them. A posterior, no-loop gastroenterostomy was performed which was somewhat difficult because of the fixed position of the stomach. The patient made a prompt and satisfactory recovery from this operation. His anemia disappeared, and he had been free from indigestion, for a period of over five years.

Perforated Duodenal Ulcer.—Dr. EDWARD W. PETERSON reported this case. This patient, a man of fifty years of age, was admitted to the Post-Graduate Hospital on April 28, to the service of Dr. Samuel Lloyd, with the diagnosis of gall-stone disease. He was operated upon the following day. Since 1902 he had suffered from digestive disturbances and had had occasional attacks of sharp pain in the epigastrium, vomiting, fever, etc. During each attack he would be confined to the bed from two or three days to a week or more. Shortly before admission to the hospital he had an attack lasting three weeks and with this attack there was a constant dull aching pain which became acute three or four hours after his evening meal. He would then become nauseated, vomiting practically all of the food taken during the day, the vomitus showing only partial digestion. Following the vomiting he would experience a feeling of relief. The pain, nausea, vomiting, etc., were but little influenced by the character of the

food or its amount. There was no hunger pain and the taking of food increased rather than lessened the discomfort. The pain did not radiate to the back or the shoulder. There was no jaundice. The radiographic study of this case before the patient entered the hospital indicated a pyloric or duodenal ulcer. The family physician was inclined to think that the trouble was due to gall-stones. Through the courtesy of Dr. Lloyd this patient was turned over to Dr. Peterson for operation. Adhesions were found binding together omentum, gall-bladder, and the pyloric end of the stomach. After freeing these the gall-bladder was found to contain no stones. The duodenum was much thickened and adherent to the under surface of the liver. Upon separating the duodenum from the liver a perforated ulcer, about the size of a ten-cent piece, was found on the anterior wall of the gut. There was also a contact ulcer on the posterior duodenal wall. The ulcer had perforated slowly and the adhesions to the under surface of the liver had prevented leakage and diffuse peritoneal infection. Owing to the much thickened condition of the duodenum and the enlarged lymph glands in the vicinity of the ulcer, the condition was thought to be malignant. An immediate frozen section diagnosis, however, showed only a chronic inflammatory condition. The pyloric end of the stomach and the first portion of the duodenum were resected. Great difficulty was experienced in closing the duodenum. A no-loop posterior gastro-enterostomy was made. The abdomen was closed with drainage at the duodenal stump. The patient's recovery was satisfactory except for the leakage from the duodenum. This was profuse and annoying for about two weeks when it ceased rather abruptly. The patient left the hospital in about four weeks; since this time he had gained rapidly in weight and strength, the gain in weight amounting to about 40 pounds. At present he weighed more than he had ever weighed in his life and was entirely free of any digestive trouble.

Resection of Joint with Resulting Function.—Dr. ASPINWALL JUDD presented this case. The patient, eighteen years of age, was operated upon four years ago for a tuberculous osteomyelitis of the elbow joint. The entire joint was involved. A resection was done, care being taken to save as far as possible the periosteal attachments of all muscles and as much as possible of the periosteal tubes even when involved in the tuberculous process to some extent. The tubes were packed with iodoform gauze, after thoroughly cleaning all the tissues with iodoform and ether, 12 per cent. The muscles with their periosteal attachments were sutured to other muscles with periosteal attachments or to surrounding structures in such fashion as to give a point of leverage for the proper functioning of those muscles. By the deposition of subperiosteal bone and dense scar tissue a false joint had been formed and the patient had 90 per cent. of function as all who would examine him might see. The strength of the arm was almost unimpaired, although it was 5 inches shorter than the other and radiographs showed not the slightest trace of the old joint. The points to be brought out in this and other cases of the same sort in which he had done a resection of this kind were the saving of the periosteal attachments, the suturing them so as to get so far as possible a muscular pull in the proper direction and the saving of the periosteal tube, thereby obtaining by means of subperiosteal bone a false joint which would act more or less like a fulcrum. Dr. Judd said he had obtained almost as good a resection in several shoulder joint cases, several elbows, and one hip. In the last case the man now drove his own automobile, using the foot of affected side in pressing the pedal.

Carcinoma of the Stomach.—Dr. JUDD presented this second patient, a woman twenty-three years of age, who had been operated upon a year ago for acute appendicitis. At that time a diagnosis of gastric ulcer was also made. The patient refused further operation. Her subsequent history showed the classic symptoms of gastric ulcer except that there was no blood at any time. She was operated upon sixteen days ago, when a hard thickened mass was found involving the greater curvature of the stomach, the pylorus, and the first part of the duodenum. The pathologist reported that it was an adenocarcinoma engrafted upon an old ulcer, and that the glands were involved for about 3 inches. The glands along the greater curvature were all involved. A resection of the pyloric third of the stomach, was made together with the pylorus and the caput of the duodenum, and all the glands along the greater curvature were removed. The glands along the lesser curvature were not involved. (When the glands along the lesser

curvature were involved it was useless to proceed with a radical removal, even if the stomach was not tied down as the mediastinal glands were always sooner or later involved.) A posterior gastroenterostomy united the stomach to the jejunum, there being no loop. Dr. Judd said he had found in the literature one case of carcinoma of the stomach occurring in an individual at the age of seventeen years and one at eleven years of age. The recovery in the case presented was uneventful and all the functions of the patient were normal.

Bone Graft (Inlay).—Dr. JUDD also presented this patient, a young man nineteen years of age, who had sustained a compound fracture of the tibia and fibula, the result of an automobile accident. He was in the hospital for about eight weeks and no operation was done on account of sepsis. The operation then done consisted in taking a graft from the crest of the opposite tibia about 1 by $\frac{1}{4}$ by 5 inches, and after making a suitable groove in the broken bone, removing detached fragments, and cleansing the site thoroughly, making fast the graft. The resulting loss of bone and tissue was about $1\frac{1}{2}$ inches. The graft contained periosteum which was sutured to the periosteum of the broken tibia. The graft united firmly to the distal portion of the tibia but failed to unite to the upper fragment. A second operation was performed at which time the fragment was found unabsorbed, firmly united below, but so freely movable above that a space of 3 inches could be produced by moving the leg. The graft and the upper portion of the tibia were freshened, the graft fastened, and plaster applied. At the present time the leg was as sound as its fellow. The point to be emphasized was that the graft, after uniting to the lower portion of the tibia, remained absolutely ununited to the upper portion and did not undergo absorption, but seemed at the time of operation as large as ever and after the freshening of its surfaces and also of the tibia united firmly. The last radiographs taken, nearly one year later, showed the graft much diminished in size but still plainly visible with much new bone at the site of the operation.

Gastroenterostomy and Occlusion of the Pylorus by Means of a Heavy Pagenstecher Thread.—Dr. WILLIAM A. DOWNES presented a young woman upon whom he had done this operation. Nine months later on account of persistent vomiting the patient was again operated upon and an enteroanastomosis performed. At this time the occluded pylorus was examined from within the stomach and seemed to be completely closed. An x-ray taken six months later showed that the pylorus had remained closed and all the bismuth passed through the gastroenterostomy opening. However, in the routine x-ray examination of the case at the end of twenty-four months bismuth was seen to be passing through the pylorus and it was very evident the occlusion had not been permanent in nature and it was for this reason the case seemed worth while reporting. Dr. Downes said he was not in favor of occluding the pylorus except in a certain type of cases. The case shown was of the kind in which there was extreme ptosis, retention of food, and constant vomiting. There was a limited field for this operation in these cases when carefully selected.

Pyloric Exclusion; an Experimental and Clinical Study.—Dr. RICHARD LEWISOHN read this paper. He stated that up to a few years ago simple gastroenterostomy was considered the method of choice for the treatment of gastric and duodenal ulcers. Most of the surgeons, however, now agreed that pyloric exclusion in some form ought to be added to this procedure in order to permanently cure pyloric and duodenal ulcers. It was a well known fact that simple gastroenterostomy did not prevent the food from passing through the pylorus and over the ulcerated area. Dr. Lewisohn stated that there were five different methods of pyloric exclusion but that none of them secured a permanent exclusion. He reported experiments with a modified Biondi method. This modification insured permanent exclusion. The technique, however, was too difficult and the method therefore should not be applied to clinical surgery. He showed the stomach of a dog operated upon according to the Biondi method and killed three months after operation. The pylorus was wide open and hardly any signs of surgical interference could be seen. He further demonstrated a human pylorus which he had resected in July, 1915. This patient had undergone a gastroenterostomy and pyloric exclusion with the string method eighteen months previously. The pylorus was patent and admitted the little finger, the

stitch being still *in situ*. He concluded that the clinical results were just as good in using the most simple method (exclusion stitch) as in the use of the most complicated method (Eiselsberg). Though the exclusion stitch did not ensure a permanent exclusion of the pylorus, it ensured a temporary one and thus effected the healing of the ulcer.

The Inefficiency of Pyloric Exclusion by Fascial Bands; an Experimental Study.—Dr. HAROLD NEUHOF read this paper in which he stated that at the present time there was no general agreement as to the desirability of complete or permanent closure, or even as to the indications for exclusion of the pylorus. It was important, however, to know what might be expected from any method. The question of permanent viability was still unsettled and was not considered in the experiments described. In these experiments two methods were employed. Either the pylorus was tightly ligated with a strip of *fascia lata* knotted about it; or the fascia, as a broad band, was sutured snugly about the pylorus and infolded by two or three tiers of sutures. The gastroenterostomies were of the no-loop kind, with large stomata. Only one, at an examination made six days after operation, was the pylorus found to be completely water tight. When the examinations were made at the end of one to three weeks it was usually found closed until the hydrostatic pressure within the stomach became high. Even in this period, however, the pylorus was found open in one experiment. It was of interest to note that the cause of the partial exclusion observed a short time after operation appeared to lie in extensive peripyloric adhesions that generally developed, rather than in the constriction made by the band. In microscopic sections the fascia was found adherent to the gastric wall, but was evidently stretched, despite its great tensile strength, by the underlying musculature. When post-mortem examinations were made one to three months after operation the pylorus either opened with moderate hydrostatic pressure or was quite patent. In the latter instance the fascial band was incorporated with the gastric wall, but it made a ring that fitted loosely about the pyloric muscle. This was evident in the microscopic sections. In short the error in the work of Bogoljubow and his followers was the brief period of observation after the operation. Only very temporary pyloric exclusions resulted from ligation with fascial bands and even this could not be expected to develop regularly. A question which naturally arose was would pyloric exclusion by fascial strips be successful if the pylorus was first crushed. A few experiments were made in order to determine this point. In one instance, two months after the operation, the pylorus remained closed with moderate, but opened with considerable, hydrostatic pressure. It was found patent without water pressure in the remaining experiments. As a last effort to establish pyloric exclusion with fascial strips in a few instances the stomach was opened near the pylorus, gauze sponges and a strong tincture of iodine was vigorously rubbed into the pyloric mucous membrane, the gastric incision was closed, and the constricting fascial band applied. These experiments were as unsuccessful as the previous ones. There were two deaths worthy of mention because they appeared to be directly ascribable to disturbed mechanical arrangements, the sequel of incomplete pyloric occlusion. At autopsy complete or almost complete retention of gastric contents was demonstrable in both of these animals. In conclusion Dr. Neuhoof stated that the experimental evidence of pyloric occlusion by fascial bands rested on incorrect observations, the pyloric closure having been examined too soon after operation. Permanent pyloric occlusion did not follow experimental ligation with fascial bands, and even temporary pyloric occlusion was uncertain after experimental ligation with fascial bands.

Lantern Slides Illustrating Roentgenographic Studies in Cases of Pyloric Exclusion.—Dr. LEON THEODORE LE WILD read this paper and exhibited lantern slides illustrating it. He stated that he had records of thirteen patients on whom an occlusion of the pylorus had been performed. In six cases the operation was performed for the relief of ulcer of the stomach in conjunction with a posterior enterostomy. In six other cases the operation was performed for relief of stasis in the stomach due to ptosis of the water-trap type. In all of these the operation was performed in conjunction with posterior gastroenterostomy. The thirteenth case was one in which a posterior gastroenterostomy had been per-

formed six years previously for relief of ulcer of the stomach, but without closure of the pylorus. To increase the efficiency of the gastroenterostomy opening, the pylorus was excluded according to the method of von Eiselsberg two months ago; the case was examined one month after operation at which time the occlusion remained. This was the only case in which the pyloric canal had not again tunneled through after closure, but the period of observation after operation of this case was a very short one, while all the other cases had been observed for a period dating back two and one-half years. The ages of the patients varied from 23 to 58 years. There were five males and eight females. From a careful study of these cases it appeared that closure of the pylorus by means of ligature, even if combined with crushing of the tissues by clamp, was incapable of insuring permanent closure. However, there seemed to be certain cases in which a temporary closure of the pylorus was of distinct benefit. In order to obtain a more permanent occlusion complete section of the stomach seemed to be necessary and if this could be combined with a resection of the diseased area it allowed the stomach to empty through the gastroenterostomy opening in a most satisfactory manner.

Election of Officers.—*Chairman*, Dr. John Douglas; *Secretary*, Dr. Seth M. Milliken.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

CALIFORNIA STATE BOARD OF MEDICAL EXAMINERS.

San Francisco, June 15-18, 1915.

ANATOMY AND HISTOLOGY.

1. Give formation and branches of the lumbar and sacral plexuses. (May use diagram.) 2. (a) Classify articulations; give a typical example of each class. (b) Discuss the hip joint, naming all muscles passing across the joint. 3. Discuss the distribution and central connections of the auditory (eighth cranial) nerve. 4. Discuss the bony thorax. 5. Discuss the pleura, giving attachments and reflections, also external markings of its boundaries. 6. Give the action of: (a) the sternocleidomastoid, singly and together; (b) the psoas magnus; (c) serratus anterior; (d) deltoid; (e) trapezius; (f) iliocostalis; (g) latissimus dorsi. 7. Describe by diagram the longitudinal section of the femur, showing outline and histologic structure showing normal development and regeneration. 8. Give the essential differences of the appearance and structure—gross and microscopic—of the mucous membrane of the duodenum, jejunum and ileum. 9. Give the histology of a medium size artery. 10. Give formation of the tributaries of the portal vein; give most inferior tributary. 11. Discuss the cervical sympathetic ganglia; give location, tributaries and branches. 12. Give histology of the mammary gland; make drawing showing typical histologic section.

PHYSIOLOGY.

1. (a) Discuss hemolysis. (b) Discuss the origin and fate of the leucocytes. 2. What is the relation of the nerves to the movements of the intestines? 3. Discuss the influence of the nervous system on respiration. 4. Define the following terms: inhibition, diffusion, osmosis, diapedesis, perimetry. 5. Discuss the metabolism of the embryo. 6. Discuss color blindness. 7. Discuss inhibition in reflex action. 8. Discuss the relation of the rods and cones to vision. 9. Discuss the variations in the volume of the brain due to respiration. 10. Discuss the sensation of hunger and thirst. 11. (a) What are the sources of uric acid? (b) Where and how is uric acid formed? 12. What effects are observed after section of a cutaneous nerve?

CHEMISTRY AND TOXICOLOGY.

1. Name and give the formulas for five salts of mercury. 2. What is the formula of hydrogen peroxide? What is its action on silver oxide; on finely divided platinum? 3. What is "bleaching powder"; its formula? How does it act as a disinfectant? 4. Define and discuss diffusion and osmosis. 5. Describe and discuss briefly HNO_3 ; its chemical and physical properties. 6. Discuss arsenic (its occurrence, properties, and toxic effects, and describe the use of one antidote). 7. Discuss lead poisoning and two effective means of overcoming the same. 8. Define "physiologic antidote" and

"chemical antidote" and give an example of each. 9. Discuss hydrargyrisms. 10. Discuss the indications and contraindications for the use of stomach pump. 11. Discuss carbolic acid poisoning and an efficient method of treatment. 12. Discuss the toxic effects of yellow phosphorus.

MATERIA MEDICA AND THERAPEUTICS, PHARMACOLOGY, INCLUDING PRESCRIPTION WRITING.

1. Name four commonly used mercury compounds (U. S. P.) and discuss briefly their therapeutic uses. 2. Discuss fully the possible therapeutic effects that would be expected of the following prescription: $\mathcal{R}$ Tinct. nucis vomicae, 5.0; fluidextracti cascarae, 10.0; tinct. cardamon comp., 25.0; tinct. gentian comp., q.s.ad. 100.0. M. Sig.: Take one teaspoonful in half glass of water t. i. d., before meals. 3. What is apomorphine? State dosage, indications, modes of administration, and action. 4. Discuss the indications and contraindications for the use of the following: $\mathcal{R}$ Kalii iodidi, 18.0; aqua dest., 60.0; syrup sarsaparilla comp., q.s.ad. 125.0. M. Sig.: Take one teaspoonful, well diluted, t.i.d., p. c. 5. Describe and discuss three different modes of administering drugs for therapeutic purposes. 6. Discuss the conditions that modify the effects of drugs. 7. (a) Discuss the dosage of drug as influenced by age, sex, size and weight of the individual. (b) Define idiosyncrasy and discuss one example. 8. (a) Discuss oleum ricini, its dosage, therapeutic action and indications. (b) Discuss three contraindications for the use of intestinal evacuants. 9. Discuss the systemic action of alcohol (internally administered.) 10. What is epinephrin? How is it administered? What are its principal effects? 11. Discuss salvarsan (its principal properties, dosage, best mode of administration, indications and contraindications). 12. Describe the bromide salt most commonly used (as to its physical properties, dosage, therapeutic action, and untoward effects).

BACTERIOLOGY AND PATHOLOGY.

1. What changes are found in a stained blood smear in primary pernicious anemia? 2. What elements might you find microscopically in the sediment of a normal urine? 3. Describe the microscopic field seen in: (a) a negative Widal reaction; (b) a positive Widal reaction. 4. What do you look for in a microscopic examination of stomach contents? 5. Define eosinophilia; name several conditions. 6. What are casts? Describe at least three varieties, and tell under what diseased conditions they are found. 7. Discuss briefly the etiology of chronic interstitial hepatitis, or cirrhosis of the liver, and describe the microscopic appearance of at least two varieties. 8. Describe embolism, infarction and thrombosis, and briefly discuss the pathology of each. 9. Define: (a) carcinoma; (b) sarcoma. Give the relative frequency of occurrence in the: (a) breast; (b) liver; (c) bone. 10. Describe the gross appearance of a bone at the site of osteomyelitis. 11. What are the causes of jaundice and how do they operate to produce this condition? 12. Define: (a) cloudy swelling; (b) atrophy; (c) malignancy.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

CALIFORNIA STATE BOARD OF MEDICAL EXAMINERS.

San Francisco, June 15-18, 1915.

ANATOMY AND HISTOLOGY.

1. The *lumbar plexus* is formed by the union of the anterior divisions of the first four lumbar nerves. The arrangement of the plexus is variable. The iliohypogastric and ilioinguinal come from the first lumbar nerve; the genitocrural comes from the first and second; the obturator comes from the second, third, and fourth; the external cutaneous comes from the second and third; the anterior crural comes from the second, third, and fourth; the accessory obturator, from the third and fourth.

The *sacral nerves*, five in number, divide into anterior and posterior nerves. The four upper sacral nerves, with the fifth lumbar, and a filament from the fourth, the two latter forming the lumbo-sacral cord, together form the *sacral plexus*. It lies upon the anterior surface of the pyriformis muscles, and is separated from the viscera, the sciatic and pudic branches of the internal iliac artery by the pelvic fascia. Its branches are: Muscular, superior gluteal, inferior gluteal, small sciatic, perforating cutaneous, pudic, and great sciatic.

2. (a) Articulations are classified as: *Synarthrodial* (or immovable), as the sutures of the skull; *Amphiarthrodial* (or slightly movable), as symphysis pubis; and *Diarthrodial* (or freely movable), as shoulder joint.

(b) The *hip-joint* is an *enarthrodial* joint, formed by the head of the femur and the acetabulum. The articular surfaces are covered with cartilage. Near the center of the head of the femur is attached the *ligamentum teres*. The *ligaments* are: (1) The capsular, which embraces the margin of the acetabulum above, and the neck of the femur below. (2) The *ileo-femoral* or *Y* ligament, which passes obliquely across the front of the joint, and is attached above to the anterior inferior spine of the ilium, and below to the anterior *intertrochanteric* line. (3) The *ligamentum teres*. (4) The *cotylod* ligament, which deepens the acetabulum, and bridges over the cotylod notch, being there called (5) the *transverse* ligament. The joint has a very extensive *synovial* membrane. It is capable of the following movements: Flexion, extension, abduction, adduction, circumduction and rotation.

Muscles which pass across the joint: Pectineus, *psaos*, *iliacus*, *sartorius*, *rectus femoris*, *gluteus maximus*, *gluteus medius*, *gluteus minimus*, *quadratus femoris*, *obturator externus* and *internus*, *gemellus superior* and *inferior*, *biceps*, *semimembranosus*, *semitendinosus*, *pyriformis*.

3. The *auditory* nerve consists of two portions:—(1) *cochlear*, or *auditory* portion, and (2) *vestibular*, or fibers whose function is to localize position. The former pass from the cochlea to the (1) *accessory auditory nucleus* in the medulla, and (2) to the *lateral acoustic tubercle* in the medulla. These fibers, by means of the *lateral fillet*, communicate with the *inferior corpora quadrigemina*. The *vestibular* fibers pass from the vestibule to the *external* and *internal dorsal nuclei* in the floor of the fourth ventricle, and by the *sensory decussation* to the *nucleus cuneatus*. *Superficial origin*, from groove between *olivary* and *restiform* bodies; *course* winds around *restiform* body, and passes forward to *internal auditory meatus*, with the *facial*; *distribution*, to *internal ear* by two branches:—The *vestibular* and *cochlear*. (Youngs *Handbook of Anatomy*.)

4. The *bony thorax* is bounded behind by the twelve *dorsal vertebrae* and the *posterior* part of the ribs; in front by the *sternum* and *costal cartilages*; on the sides by the ribs and *intercostal spaces* with the *intercostal muscles*. It is *conical* in shape, being broadest below. It contains the chief organs of *respiration* and *circulation*. The aperture transmits the *sternohyoid* and *sternothyroid muscles*, *trachea*, *esophagus*, *thoracic duct*, *inferior thyroid veins*, *longus colli*; *innominate*, *left common carotid*, *left subclavian*, *internal mammary*, and *superior intercostal arteries*; *right* and *left*, *innominate veins*; *vagus*, *phrenic*, *cardiac*, *sympathetic*, and *left recurrent laryngeal nerves*; the apex of each lung also projects through the superior opening. Below is the *subcostal angle*.

5. "The *pleuræ* are two serous sacs enclosing and investing the lungs. Each *pleura* consists of a *visceral* and *parietal* layer. The *visceral* portion covers the lungs, and the *parietal* layer lines the inner surface of the chest walls, the upper surface of the diaphragm, and the sides of the pericardium. The *visceral* and *parietal* layers of the corresponding *pleura* become continuous in front and behind the root of the lung; and below the root a fold, the *ligamentum latum pulmonis* extends downward along the inner surface of the lung to the diaphragm. The *mediastina* are formed by the *visceral* layers of each side approaching one another toward the median line.

"The limits of the *parietal pleuræ* are as follows: Each extends upward into the neck, forming a *domelike* process over the apex of the lung about two inches above the first *costal arch*; from this the *pleura* passes downward and forward to the *posterior* aspect of the *sternoclavicular joint* of each side and meets its fellow in the midline at the *manubriogladiolar articulation*; they pass down together to level of fourth *costal cartilages*, where *right pleura* passes vertically to level of seventh *right costal cartilage* in midline; then outward, crossing ninth rib in *midaxillary line*; then downward and backward along eleventh rib to reach spine at neck of twelfth rib. Behind, it passes upwards on right side of bodies of *vertebræ* to apex. At level of fourth *costal cartilage* the *left pleura* arches outwards, leaving uncovered part of anterior surface of *pericardium*, and lying about $\frac{3}{4}$ inch from the margin of *sternum*, to reach seventh *costal cartilage*, where it

follows same line as on right, but is placed at a slightly lower level." (*Aids to Anatomy*.)

6. *Sternocleidomastoid*: The action of one draws the head toward the shoulder of the same side and turns the face toward the opposite side. The two acting together flex the head upon the neck; and, if the head is fixed, they raise the thorax.

Psoas magnus flexes the thigh on the pelvis, bends the pelvis forward, helps in maintaining the body in the erect position, and assists in raising the body from the recumbent position.

Serratus anterior lifts the scapula forward and raises its vertebral border; it aids in the act of pushing, and in raising the acromion and supporting weights on the shoulder, and in raising the arm to the vertical position.

Deltoid aids in raising the arm from the side, also in drawing the arm forward and backward.

Trapezius raises clavicle and scapula, also moves them downward and backward; draws head backward, and flexes it to same side.

Iliocostalis extends the spinal column, maintains it in the erect position, and bends it backward.

Latissimus dorsi depresses the humerus, adducts it, draws it backward, and rotates it inward.

7. A cross-section of a bone shows *Haversian canals*; around these the bone is arranged in rings or *lamellæ*; between these are spaces (*lacunæ*) in which are bone corpuscles. Each canal is connected with the *lacunæ* which are concentric with it, and the *lacunæ* with one another by means of fine canals (*canaliculi*) into which project processes of the bone corpuscles. A *Haversian canal* with its *lamellæ*, *lacunæ*, bone corpuscles, and *canaliculi* form a *Haversian system*. In a section of bone several of these systems may be seen, the spaces between them being occupied by *interstitial lamellæ*. *Lamellæ* which are on the surface of the bone, parallel with its circumference, are *circumferential lamellæ*. A longitudinal section of bone shows the *Haversian canals* to be what their name indicates, channels running through the bone. Their communications with one another are also seen. In each canal are an artery and a vein. If a piece of bone is treated with dilute nitric acid, so as to dissolve the lime salts which it contains, or by some other method of *decalcification*, a small portion may be torn off, which upon examination shows the fibrous structure of the *lamellæ*. Such specimens also show the *perforating fibers of Sharpey*, which hold the *lamellæ* together; elastic fibers may also be observed.—(*Raymond's Physiology*.)

8. *Duodenum*: *Valvulæ conniventes*, except in the first inch or two; villi; crypts of Lieberkühn; solitary glands; ducts of Brunner's glands; orifice of common bile duct and pancreatic duct. *Jejunum*: *Valvulæ conniventes*; numerous villi; crypts of Lieberkühn; solitary glands; Peyer's patches in lower half. *Ileum*: *Valvulæ conniventes*, few in upper half, none in lower half; few villi; crypts of Lieberkühn; solitary glands; Peyer's patches.

9. A medium-sized artery consists of an endothelial tube covered with three coats. The inner coat consists of endothelial cells placed upon a layer of fibro-elastic tissue. Around this is a wavy band of yellow elastic tissue. The middle coat consists of muscle, elastic tissue and white fibrous tissue. The smooth muscle tissue is circularly arranged and there is very little elastic tissue. The external coat consists of fibro-elastic tissue and contains the nutrient vessels, nerves, and lymphatics.

10. The *portal vein* is made up by the junction of the superior mesenteric and splenic veins. The tributaries of the portal vein are the splenic, superior mesenteric, gastric, pyloric, cystic, and umbilical. The *splenic* receives the *vasa brevia*, left gastro-epiploic, pancreatic, and inferior mesenteric veins. The *superior mesenteric* receives the intestinal, ileocolic, colica dextra, colica media, right gastro-epiploic and pancreaticoduodenal veins. The most inferior tributary is the inferior mesenteric vein.

11. *Cervical Sympathetic Ganglia*.—The cervical ganglia consist of three—superior, middle, inferior—of which the superior is the largest and the middle the smallest. These are connected above with the cranial ganglia, below with the thoracic ganglia, and communicate with each other. The *superior cervical ganglion* lies opposite the second or third cervical vertebra, behind the internal carotid artery. It is connected with the middle ganglion, the upper four cervical, and tenth and twelfth cranial nerves, distributes branches to the carotid (internal), cavernous, and pharyngeal plexuses,

and gives off the *superior cardiac nerve* to the cardiac plexus. The *middle cervical ganglion* lies upon inferior thyroid artery, opposite fifth cervical vertebra. It is connected with the upper and lower ganglia and spinal nerves, and gives off the *middle cardiac nerve* to cardiac plexus. The *inferior cervical ganglion* lies internal to the superior intercostal artery, below the last cervical vertebra. It is connected to the middle ganglion, first thoracic, lower cervical nerves, forms the vertebral plexus, and gives off the *inferior cardiac nerve* to cardiac plexus. (Young's *Handbook of Anatomy*.)

12. "The mammary gland is a multiple alveolotubular organ. It is composed of from fifteen to twenty individual compound glands. Each of these possesses its own excretory duct, that has its own opening in the nipple. The entire organ is covered by skin. Each gland consists of lobes and lobules separated and supported by white fibrous and adipose tissues. All of the individual glands are further bound together in the same manner. The ducts converge and end in the nipple, which forms a small projecting mass. Each lobule consists of a number of acini which are tubular or alveolar in structure. The number of these depends upon the state of activity. In the gland of pregnancy, the acini are very numerous, and are lined by simple columnar or cuboidal cells, in which are accumulated the fat globules that form the important constituent of the milk. These cells rest upon a basement membrane, but in places are separated therefrom by peculiar elements called basket cells, which are compared to the smooth muscle tissue of the sweat glands. The ducts are lined by simple columnar cells which rest upon a basement membrane, outside of which circular bundles of white fibrous tissue are to be found. These ducts unite to form the main secretory duct of the individual glands; each main duct dilates to form a small ampulla or sinus lactiferus, before the nipple is reached." (Radasch's *Compend of Histology*.)

PHYSIOLOGY.

1. (a) *Hemolysis*. "The act of discharging the hemoglobin from the corpuscles so that it becomes dissolved in the plasma is designated as hemolysis, and substances that cause this action are spoken of as hemolytic agents. A number of such agents are known; but, although the results of their action are the same, so far as the hemoglobin is concerned, the way in which they bring about this result must vary greatly. Some of the known methods of producing hemolysis, or rendering the blood 'laky,' are as follows: (1) By the addition of water to the blood or by diminishing in any way the concentration or osmotic pressure of the plasma. (2) By adding ether or chloroform. (3) By the addition of soaps or of the higher fatty acids, especially the unsaturated acids. (4) By adding bile or solutions of the bile-salts. (5) By adding amyl alcohol. (6) By adding the serum from the blood of certain animals. (7) By adding saponin or sapotoxin. (8) By the addition of an excess of alkali. (9) By various toxins found in snake venom or in the serum of other animals or among the products of bacterial activity (natural hemolysins), or by similar organic substances produced within the body by the process of immunizing. Some of these hemolytic agents, such as ether, bile-salts, and soaps, probably effect their action by their power of uniting with the lipid elements (lecithin, cholesterol) in the stroma of the corpuscles. The framework of the corpuscles is thus altered so that the hemoglobin is set free. (Howell's *Physiology*.)

(b). *Origin of leukocytes*: They are found in the spleen, lymph glands, and lymphoid tissue; also from the leukocytes by direct cell-division in the blood stream; the eosinophiles may be derived from the bone marrow.

Their *fate* is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells.

2. "The *small intestine* is supplied by the vagus and the splanchnic nerves, and although the intestinal movements are independent of the central nervous system it can be shown that these nerves exert a controlling influence. Stimulation of the vagus is followed by contraction of the muscle of the intestinal wall after a preliminary relaxation, but has no effect on the ileocolic sphincter. Stimulation of the splanchnic nerve results in a general relaxation, but in contraction of the ileocolic sphincter. The vagus and sympathetic fibers to the small intestine are distributed in the first instance to the myenteric nerve plexus lying between the layers

of the muscular coat. The influence of the central nervous system on the intestinal movements is shown in their inhibition as a result of pain, and also in their exaggeration in consequence of emotional conditions.

"The *large intestine* receives its nerve supply from the sympathetic system and from the pelvic visceral nerves or *nervi erigentes*. The sympathetic fibers form the inferior mesenteric nerves, running from the inferior mesenteric ganglion to the ascending, middle, and transverse colon, and the hypogastric nerves pass from the same ganglion to the rectum. Stimulation of the sympathetic nerves causes inhibition of the tone of the intestinal wall and cessation of the rhythmic movements. Stimulation of the *nervi erigentes* causes contraction of the whole length of the colon. The sympathetic is therefore inhibitory and the pelvic visceral nerves are motor in function." (Bainbridge and Menzies' *Essentials of Physiology*.)

3. "The respiratory center is situated in the medulla, and is in reality made up of two centers, one for each side, so that, although anatomically connected and ordinarily acting together, yet if one center is broken up, while the respiratory movements on that side cease, those on the other side continue. Besides this double character of the center, each half is made up of an *inspiratory* and an *expiratory* center. The respiratory center is both an *automatic* and a *reflex* center—i. e., it sends out *spontaneously* impulses which result in movements of the respiratory muscles, constituting its *automatism*; and it may also be excited *reflexly*—i. e. by impulses reaching it from without. Its reflex character is most marked, and it is doubtless as a reflex center that its function is ordinarily performed." —(Raymond.)

The normal stimulus is the presence of carbon dioxide in the blood; impulses also pass along the vagus nerves from the lungs; further, there are impulses from the brain and various afferent nerves, all of which are capable of modifying the respiratory movements.

4. *Inhibition* is the voluntary or involuntary restraint of a reflex action; it is due to the action of the higher nerve centers.

Diffusion is the intermolecular penetration of two or more gases when in contact with each other.

Osmosis is the passage of liquids and of substances in solution through a membrane or porous substance.

Diapedesis is the passage of the red blood cells through the unruptured wall of blood-vessels; the term is also used for the similar action of the blood as a whole and of the white corpuscles.

Perimetry is measurement of the field of vision.

5. *Metabolism of the embryo*. (1) "At first the ovum absorbs nutriment simply through the vitelline membrane, while passing through the Fallopian tube. The nutrient material is supplied by the secretion of the tube itself, or may consist in part of seminal fluid introduced from without. (2) The vitellus is absorbed by the entoderm lining the umbilical vesicle and alimentary canal, and later it is absorbed and conveyed into the body of the embryo by the bloodvessels of the area vasculosa. (3) When the contents of the umbilical vesicle are exhausted, the chorionic villi appear and take up nourishment from the uterine decidua, with which they are in contact. (4) With the disappearance of villi in the chorion laeve, the villi of the decidua serotina develop into the placenta, where they take up nutriment from the maternal blood with which they are surrounded. (5) The placenta not only affords nutriment to the child, but is also its respiratory organ. The umbilical arteries carry blue (venous) blood to the placenta, where carbonic acid gas is given off to the maternal blood and oxygen taken in from it, so that the umbilical vein brings back arterial (red) blood to the fetus. The placenta is also an organ of excretion for the infant. Recently the placenta has been credited with a selective function, by which it has power to select from the maternal blood such materials as may be required by the fetus at different periods of pregnancy." (King's *Manual of Obstetrics*.)

6. "The explanation of color-blindness varies according to the theory of color-vision which is accepted. According to the Young-Helmholtz theory, a red-blind person is deficient in the red, and a green-blind person in the green, visual substance of the retina, or else, if these substances are present, all the rays, irrespective of their wave-lengths, stimulate them. In accordance with the Hering theory, those who are red-blind or green-blind lack the red-green visual substance and possess yellow-blue. On this theory there is no difference between red-blindness and green-blindness, but, as

a matter of fact, this is not the case. If the Franklin theory is accepted, then the explanation in the case of the red- and green-blind would be that the white-black, or gray, visual substance had developed into the yellow-blue, but had been arrested in its development before the stage of red-green had been reached. It may be said that objections may be advanced to all the theories, and that no one accounts for all the observed facts." (Raymond's *Physiology*.)

7. *Inhibition.* "Reflexes may be restrained or completely inhibited by impulses, voluntary or involuntary, from the higher nerve centers. If a reflex is elicited in a frog from which the cerebral hemispheres have been removed, and then a crystal of common salt is applied to the optic lobes and the stimulus is repeated, the reflex movement may not occur, owing to inhibitory impulses resulting from the stimulation caused by salt. A reflex act, which is in progress, may also be checked or inhibited by the advent of another stimulus to the central nervous system. Further, inhibition forms a constituent of many reflex actions, the movement of certain muscles being accompanied by the simultaneous inhibition of others."—(Bainbridge and Menzies' *Essentials of Physiology*.)

8. The rods and cones are both concerned in vision, but they differ in structure and in function. The rods are most abundant at the periphery of the retina and the cones in the central area. The generally accepted theory is that the rods are most concerned with vision in dim lights, and with the form of objects, and that the cones are chiefly concerned with vision in ordinary light and with the color of objects.

9. Such variations as can possibly take place in the volume of the brain are due to the possibility of displacement of the cerebrospinal fluid. This is said to be due to changes in the arterial pressure, and also to interference with the venous outflow from the skull during expiration. The swelling of the brain is sometimes synchronous with expiration, and the shrinking of the brain with inspiration. But the reverse of these conditions has also been observed.

10. *The sensation of hunger* is referred to the region of the stomach, and is the outcome of nervous impulses from the stomach. *The sensation of thirst* is located in the back of the pharynx. Both of these sensations are localized expressions of a general need of the tissues of the body for food and drink. The exact seat of the sensations is unknown; and thirst is more painful and more urgent than hunger.

11. Uric acid belongs chemically to the group of substances called "purins," uric acid being trioxypurin. The uric acid which is derived from the purin bodies contained in the food is called "exogenous" uric acid, while that which comes from the breaking down of the tissues of the body which contain aminopurins and oxypurins or nucleins is called "endogenous" uric acid. It is formed in the liver, spleen, and other tissues, as the result of oxidation of certain purin bases which are derived as just mentioned (exogenous and endogenous). These bases are set free by the action of an intracellular enzyme (nuclease) of wide distribution. The subject is summed by Lyle, as follows:

"Putting the series of changes by which uric acid is formed from the nucleoprotein of the diet (exogenous metabolism), or the nucleoprotein of the tissues (endogenous metabolism), into schematic form: (1) Nucleoprotein is split into protein and nuclein; nuclein is split up with the production of adenine and guanine by the endo-enzyme nuclease; adenine and guanine are deamidized with the production of hypoxanthine and xanthine respectively, by the activity of adenase and guanase and uric acid is produced by the oxidation of hypoxanthine and xanthine, due to the activity of xanthine oxidases."

12. "After section of a cutaneous nerve all cutaneous sensations are lost, but there remain the sensations of deep pressure and of pain due to deep pressure, which depend on stimulation of the afferent fibers in the muscles. During regeneration of the divided nerve, the first sensations to return are those of pain, of heat for temperatures above 38° C., and of cold for temperatures below 24° C. These are the protopathic sensations, and they return from seven to twenty-six weeks after the division of the nerve. Tactile localization and discrimination, the accurate localization of pain in the skin, and the sense of heat and cold between 37° C. and 25° C., are recovered in from one to two years after the nerve section, and constitute the epicritic sensations."—(Bainbridge and Menzies' *Essentials of Physiology*.)

CHEMISTRY AND TOXICOLOGY.

1. *Five salts of mercury:* Mercurous chloride, Hg_2Cl_2 ; mercuric chloride, HgCl_2 ; mercurous iodide, Hg_2I_2 ; mercuric iodide, HgI_2 ; mercuric sulphate, HgSO_4 .

2. The formula of hydrogen peroxide is H_2O_2 . When it is brought into contact with silver oxide both substances are violently decomposed, water and silver remaining. Platinum decomposes it into water and oxygen.

3. *Bleaching powder* is either a mixture of calcium chloride and calcium hypochlorite, $\text{CaCl}_2 + \text{Ca}(\text{ClO})_2$; or a definite compound with the formula $\text{CaCl}(\text{ClO})$. It acts as a disinfectant by reason of the chlorine which is liberated when treated by even the weakest acids or by boiling water. The chlorine in the presence of water decomposes the latter, and the nascent oxygen then attacks the matter which requires the disinfection. Hence it acts as an indirect oxidizing agent.

4. *Diffusion and Osmosis:* "When two gases are brought into contact a homogeneous mixture of the two is soon obtained. This interpenetration of the gases is spoken of as diffusion, and it is due to the continual movements of the gaseous molecules to and fro within the limits of the confining space. So also when two miscible liquids or solutions are brought into contact a diffusion occurs for the same reason, the movements of the molecules finally effecting a homogeneous mixture. If the two liquids happen to be separated by a membrane diffusion will still occur, provided the membrane is permeable to the liquid molecules, and in time the liquids on the two sides will be mixtures having a uniform composition. Not only water molecules, but the molecules of many substances in solution, such as sugar, may pass to and fro through membranes, so that two liquids separated from each other by an intervening membrane and originally unlike in composition may finally, by the act of diffusion, come to have the same composition. Diffusion of this kind through a membrane is frequently spoken of as dialysis or osmosis." (Howell's *Physiology*.)

5. *Nitric acid*, when pure, is a colorless liquid with a strong acid taste and reaction; it gives off white fumes in damp air. When exposed to air and light or when strongly heated, it is decomposed into nitrogen tetroxide, water and oxygen. It is a powerful oxidizing agent and destroys most organic substances. Most metals dissolve in it, with the formation of nitrates. The commercial acid is impure, yellowish in color, and contains about 40 to 64 per cent. of pure HNO_3 . The fuming nitric acid is of a reddish yellow color and contains oxides of nitrogen. The pharmacopœial acid contains about 70 per cent. of HNO_3 , and the diluted form about 10 per cent.

6. *Arsenic* occurs free in small quantities, but chiefly in combination in the sulphides (orpiment and realgar), and in arsenical iron pyrites. Arsenic is a brittle, crystalline solid, or an amorphous powder. Its vapor gives off the odor of garlic; it is insoluble in water and other liquids; when heated, it is converted into the trioxide. Elementary arsenic is not poisonous so long as it remains such, but in contact with water, or saliva, it becomes arsenic trioxide which is soluble and poisonous.

The symptoms of acute arsenical poisoning: "In acute cases the symptoms usually begin in from twenty to forty-five minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities." (Witthaus' *Essentials of Chemistry*.)

The stomach should be emptied, an emetic given if necessary, and the chemical antidote administered. The latter is freshly prepared solution of ferric hydroxide, which acts by producing the insoluble ferric arsenate.

7. The most common sources of lead poisoning are the following: "The contamination of drinking water from lead pipes. Contamination of articles of food or drugs by contact with leaden vessels, or from being enclosed in tinfoil containing an excess of lead. Drinking beer, cider, etc., which has been drawn through leaden pipes or allowed to stand in pewter vessels. The ingestion of constant handling of lead or its compounds, as the acetate, nitrate, carbonate (white lead—painter's colic), Goulard's extract, etc. The use of hair dyes containing lead."

Lead poisoning causes: Metallic taste, dryness of throat, thirst, severe, colicky abdominal pains, particu-

larly in umbilical region; pulse feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of lower extremities; convulsions; tetanic spasms and (in chronic cases) wrist drop.

The *treatment* consists in administering magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic, or by the use of the stomach tube.—Potassium iodide is also given to aid in the elimination of the lead.

8. A *physiological antidote* is one that acts as such by combating the physiological action of the poison, as belladonna for opium poisoning.

A *chemical antidote* is one which acts as such by uniting chemically with the poison and thus converting it into a harmless or insoluble compound, as freshly prepared ferric hydroxide solution for arsenic poisoning.

9. *Hydrargyrisim*. "The first symptoms of salivation are fetid breath, swollen and spongy gums, having a bluish line along their margins, stomatitis, sore and loosened teeth, inflamed and tender salivary glands pouring out a peculiar, thin saliva of foul odor in large quantity, and a metallic taste in the mouth. Emaciation, pallor, edema, ulcerated skin, erythematous, vesicular, or pustular eruptions, headache, insomnia, neuralgia, tremor through paresis of the muscles of the head and extremities, epilepsy, coma, and convulsions may ensue. An influenzal condition is not uncommon. Salivation is most readily produced by blue mass, next by calomel, and less easily by gray powder. Children are not easily salivated. Inhalation of mercurial vapors is likely to affect the nervous system most; its internal administration and that by inunction are more likely to produce salivation. Treatment consists in the withdrawal of the mercury, antiseptic mouth washes, particularly the potassium chlorate, and, later the use of the iodides as eliminatives. Poisoning by the bichloride requires the prompt oral administration of large amounts of albumin, the whites of eggs being most easily obtained. The stomach should be washed out, external heat applied about the body, and stimulants to the respiration and circulation given. If death does not ensue at once the organic changes in the gastro-intestinal tract, such as strictures, sloughs, and destruction of the peptic glands and ulceration, generally cause a protracted convalescence, or may eventually result in a fatal issue." (*Cyclopedia of Medicine and Surgery*.)

10. The stomach pump or tube is indicated in all cases of poisoning (except corrosives), to remove the poison from the stomach, and also as an aid in washing out the stomach. Some poisons (such as opium) are excreted into the stomach, and such lavage is then necessary. *Contraindications* are: Corrosives (when there is danger of perforating the esophagus or stomach), and when the poison is in solid form and in large pieces (as meat, cheese, fish, etc.)

7. *Symptoms of carbolic acid poisoning*: Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

The *treatment* consists in administering white of egg, sodium sulphate, or saccharated lime, followed by lavage. Alcohol is said to be antidotal. At one time alcohol was much used; just now the older remedies (such as sodium sulphate) are more relied on. Soluble sulphates form with carbolic acid the insoluble sulphocarbolates, which can be removed by lavage.

12. *Symptoms of acute phosphorus poisoning*: "Eructation of gas having the odor of garlic. The mouth, when observed in the dark, is frequently faintly luminous (phosphorescent). After several hours pain in the throat, a sense of heat in the epigastrium, nausea, and vomiting. The vomited matters are sometimes bloody, and frequently luminous when agitated in the dark. The abdomen is tender, and there are diarrhea and colicky pains. After one or two days these symptoms cease, there remaining only pain in the back and limbs and a feeble pulse. Death sometimes occurs suddenly in from two to four days. Usually about the fourth day the patient becomes jaundiced, suffers from headache, insomnia, and retention of urine, rapidly becomes delirious and comatose, and dies." (From *Witthaus' Essentials of Chemistry and Toxicology*.)

Fatal dose: The minimum fatal dose is not determined; it is small, being probably less than one grain. *Fatal period*: From a few hours to several days.

Treatment: By an emetic or the stomach tube remove from the stomach all of the poison which has not been absorbed; then give old French oil of turpentine or potassium permanganate; the food must be free from fats and oils.

Chronic phosphorus poisoning occurs chiefly among those engaged in the manufacture of matches. The symptoms are much the same as in acute poisoning, but less severe. But, in addition, there are pain in the joints, wasting of the body, perioritis (particularly of the lower jaw) followed by necrosis.

This form of poisoning may be prevented by strict cleanliness and ample ventilation of the work places, frequent cleansing of the mouth with a weak solution of sodium carbonate, and the prohibition of the use of yellow phosphorus in the manufacture of matches.

MATERIA MEDICA AND THERAPEUTICS, PHARMACOLOGY, INCLUDING PRESCRIPTION WRITING.

1. MERCURY. (1) Hydrargyri chloridum mite (calomel), dose gr. ss to x; used in syphilis, as a lavative or purgative, in congested or cirrhotic liver, in diarrhea, and as a diuretic. (2) Hydrargyri chloridum corrosivum (corrosive sublimate), dose gr. 1/60 to 1/30; used as an antiseptic, disinfectant, antiparasiticide, in syphilis, interstitial nephritis. (3) Liqueur arseni et hydrargyri iodidi (Donovan's solution), dose mgv ; used as an alterative. (4) Hydrargyrum ammoniatum (ammoniated mercury), only used externally, and employed in ozena, psoriasis, tinea, and other skin affections.

2. In the doses indicated, the tincture of nux vomica as well as the compound tincture of cardamom and compound tincture of gentian will act as a mild bitter tonic, stimulating the appetite and the flow of saliva and of gastric juice. The fluid extract of cascara will keep the bowels open. As a consequence of increased appetite and improved gastro-intestinal activity there should follow an improvement in nutrition and strength, in the case of a patient convalescing from illness or suffering from simple debility or anemia.

3. Apomorphine is an artificial alkaloid obtained from morphine by the action of hydrochloric acid. Its chief use is an emetic, particularly in cases of poisoning, or where the stomach should be emptied promptly; it has also been used in bronchial catarrh, as an expectorant. As an emetic, it should be given hypodermically in doses of 1/10 grain, and the solution should be freshly prepared; as an expectorant, the dose is 1/40 to 1/25 grain, by mouth. It is contraindicated for children. It has also been used as a sedative in epilepsy and mental disease, and as a hypnotic.

4. *Indications*: Aneurysm, hypertension, arteriosclerosis, chronic asthma, emphysema, syphilis of the nervous system, pleurisy, pericarditis.

Contraindications: Bronchitis in old people, pulmonary tuberculosis, edema of the glottis, and idiosyncrasy.

5. *Three different methods of administering drugs*:

(1) *By the mouth*. This is the most common method. Drugs may be administered by the mouth for their local action on the mouth, throat, stomach, or intestines, or for the purpose of being absorbed. When it is desired to influence the mouth or throat, the remedy is generally given in the form of a lozenge, and the patient advised not to take food or water for at least an hour afterward. Remedies intended to act directly on the mucous membrane of the stomach should be given when the stomach is empty; that is, half an hour or an hour before meals. Drugs intended to exert a direct influence on the intestine should be given two or three hours after meals, and preferably in firm pills. Sometimes such pills are coated with a substance like keratin that will resist the action of the gastric juice. (2) *Hypodermic method*. This consists in injecting medicinal solutions into the subcutaneous tissue by means of the hypodermic needle and syringe. The advantages of this method are the great rapidity with which absorption is effected, and the certainty of securing the action of the entire dose, since partial destruction of the remedy by the digestive organs is avoided. The disadvantages of this method are the pain inflicted, the liability of causing abscesses, and the risk of throwing the solution directly into a vein. The alkaloidal salts, on account of their small bulk, are especially adapted for hypodermic use. Some remedies, such as toxins and antitoxins, are effective only when administered subcutaneously. (3) *Inhalation*. Volatile drugs are rapidly absorbed from the respiratory tract, and this method is especially employed for the administration of drugs which induce general anesthesia, such as

ether, chloroform, and nitrous oxide. The effect of other volatile substances, like amyl nitrite, is also secured by inhalation. (From Stevens' *Materia Medica*.)

6. *Conditions which modify the effects of drugs are:* Age of the patient, sex, race, body weight, temperament, disease, temperature, habit, idiosyncrasy, method of administration, time of administration, preparation of the drug, and dose. *Habit:* With many drugs continuous use induces toleration; this is particularly true of opium. *Idiosyncrasy:* This is a peculiar susceptibility or insusceptibility of one or more of the tissues to the influence of certain drugs. Less than one-fourth of a grain of calomel has been known to induce salivation. The smallest dose of quinine will in some individuals cause a rash. *Cumulative action:* This is the property which some drugs have, after they have been given for a certain length of time, of producing a severe and more or less sudden effect. It is probably due in most instances to an accumulation of the drug in the tissues; excretion, for one reason or another, being less rapid than absorption. In some cases, however, it may depend upon irregular absorption, a large quantity of the drug suddenly entering the circulation from the alimentary canal where, owing to some accidental condition, there has been an undue accumulation. (From Stevens' *Materia Medica*.)

7. *To determine the proper dosage for a child:* Let x = the age of the patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

Sex: Women generally require smaller doses than men, about four-fifths.

Size and weight: This is comparatively unimportant, but as a rule a very heavy muscular individual will require a larger dose than one of slighter build and weight.

Idiosyncrasy: See above, answer to question 6.

8. *Oleum ricini*, or castor oil is a fixed oil derived from the seeds of the *Ricinus communis*. It is used as a simple purgative, an emollient, a lubricant, and the leaves of the plant are said to have a galactagogue effect when applied to the breasts. The dose is about four fluid drachms. It is indicated wherever a purgative is required, and particularly where it is desirable that there shall be no irritation, as after operations, after labor, in cases of piles, to empty the intestinal tract in children. It is not adapted to cases of chronic constipation. With balsam of Peru it makes a good surgical dressing.

Intestinal evacuations of a strong nature are contra-indicated: In pregnancy, as some of them (aloes, for example) might bring on a miscarriage; in very feeble patients and infants, for fear of still further weakening them; and in inflamed conditions of the intestinal tract and peritonitis and appendicitis, also in intestinal obstruction.

9. *Alcohol* sharpens the appetite, is a digestant, a diuretic, a diaphoretic, is slightly antipyretic; it increases the force and rate of the heart beat and pulse; it is a vasodilator, especially to the vessels of the skin; it causes an increase in the blood pressure; it is at first a slight nervous stimulant, but afterward is a depressant; in large doses it is a narcotic, and then causes a reduction of body temperature.

10. *Epinephrin* is the active principle of the suprarenal glands; it exists only in the medulla of these glands. It is generally administered in the form of a 1 per cent. solution, in doses of 10 to 50 minims. It is a cardiac stimulant, is a strong vasoconstrictor, and raises blood pressure, diminishes peristalsis, and depresses the respiratory center.

11. *Salvarsan*, or dioxy-diamido-arseno-benzol dihydrochloride; also called arsenobenzol, "Ehrlich-Hata," or 606. Its formula is $C_6H_3O_2N_2As_2(HCl)_2$, and it is supposed to have the constitution:

It is a bright yellow powder, slowly soluble in water,

has an acid reaction, contains about 34 per cent. of arsenic, is used in treatment of syphilis, but is in the experimental stage only. It would be well not to give up the older remedies yet, and not to believe all the newspaper reports on this remedy. Up to the present it seems to be uncertain whether to use the substance in a solution or in an emulsion, also whether it should be administered into a muscle, into a vein, or under the skin. Further, there are certain contraindications; and bad results have followed its use (or abuse).

Salvarsan is indicated in: "(a) Early cases of syphilis in which contagious manifestations are appearing in rapid succession, in spite of efficient mercurial medication. (b) Cases in which, for family or social reasons, it is of special importance to limit the production of infective material or cause the disappearance of symptoms in the shortest possible time. (c) Cases in which the symptoms are recalcitrant to the action of mercury, or in which, from idiosyncrasy, that drug cannot be exhibited in sufficient dose. (d) Cases of syphilophobia and syphilomania, whether showing symptoms or not; its psychic action in these instances being of greater importance than its therapeutic effect. (e) Very early cases of the sequelæ of the luetic infection, before organic changes have occurred."

Salvarsan is contraindicated in: "(a) Cases that are doing well, i.e. in which the disease is pursuing its normal mild course under ordinary medication. (b) Cases with serious organic lesions of the eyes, kidneys, heart, or other internal organs. (c) Cases with postsyphilitic or parasyphilitic disease of the internal organs, more especially of the nervous system."—(*Progressive Medicine*.)

12. *Potassium bromide* occurs as a granular powder or as cubical crystals; it is white or colorless, odorless, and has a strong salty taste. It is soluble in about 1.5 parts of cold water, and in less than 1 part of boiling water. Dose is about 15 grains. It is a gastrointestinal irritant; it depresses the cerebrospinal system and also the heart, diminishes reflex irritability. Large doses cause bromism, which is characterized by an acne like eruption, fetid breath, anemia, gastric disturbances, mental depression, muscular weakness, loss of memory, sexual weakness, and general apathy.

BACTERIOLOGY AND PATHOLOGY.

1. In *primary pernicious anemia*, the blood shows a great diminution in the number of red corpuscles, also a variation in the size and shape of these corpuscles; many of them are also nucleated; the leucocytes are somewhat diminished in number.

2. In the *sediment of a normal urine*, we might find uric acid, urates, calcium oxalate, phosphates, cholesterol, hippuric acid, leucin, tyrosin.

3. In a *negative Widal reaction* the bacilli do not gather into groups and lose their motility.

In a *positive Widal reaction* the bacilli gather into groups or "clump," and lose their motility.

4. In a *microscopic examination of stomach contents*, we look for pus cells, yeast cells, sarcinae, red blood corpuscles, and bacteria, chiefly the *Boas-Oppler bacillus*.

5. *Eosinophilia* means an increase in the blood of the number of eosinophiles; it occurs in myelogenous leukemia, filariasis, trichiniasis, osteomalacia, asthma, and certain skin diseases.

6. *Casts* are moulds of parts of the uriniferous tubules of the kidneys; they are usually composed of albuminoid substances, but may have, in addition, epithelial cells, blood corpuscles, or fat globules. *Blood casts* are composed of coagulated blood and blood cells, or are hyaline casts covered with red blood cells. They occur in hemorrhagic conditions of the kidneys. *Hyaline casts* are clear, translucent cylinders, often so pale as to be hardly visible. They are present in all forms of nephritis, in renal congestion, and sometimes in health. *Waxy casts* are much like hyaline casts, but are larger, yellowish in color, and more readily visible. They are present in chronic parenchymatous nephritis.

7. *Cirrhosis of the Liver* is caused by the prolonged use of alcoholic stimulants, malaria, syphilis, passive congestion, irritation of the bile ducts, and (possibly) the uric acid diathesis. "Atrophic cirrhosis begins with hyperemia of the connective tissue (Glisson's capsule) and enlargement of the liver results from the development of brownish-red connective tissue elements. The hypertrophied connective tissue presses upon the hepatic cells, causing them to undergo fatty degeneration. As this process advances the organ becomes reduced in size and more dense, and its surface is covered with numerous small nodules ('hob-

nails'). The hepatic and portal circulation is obstructed from obliteration of their respective radicles. The changes in the hepatic structure interfere with the venous circulation of all the abdominal viscera, resulting in venous congestion of the stomach, pancreas, intestines, and peritoneum, and enlargement of the abdominal veins. The hepatic peritoneum is thickened and opaque, and adhesions are formed between the liver and diaphragm, gall bladder and stomach. On section of the liver, firm fibrous tissue is found in abundance distributed between the lobules.

"*Hypertrophic cirrhosis* occurs in younger individuals than the preceding and does not seem to be dependent upon alcohol for its production. The organ is yellowish in color and remains enormously enlarged throughout its entire course. The newly formed connective tissue shows very little tendency toward contraction or toward compression of any of the branches of the portal vein. The connective tissue is developed to a greater extent within the lobules and thus produces obstruction of the biliary channels and consequent jaundice. By some observers it is claimed that there is a new formation of biliary capillaries and a proliferation of the liver cells."—(Hughes' *Practice of Medicine*.)

8. A **THROMBUS** is a blood clot formed in the blood-vessels during life. The process is called thrombosis. *Causes:* Changes in the blood current; changes in the vessel wall; anything within the blood current not covered with endothelium. Generally more than one of these conditions are present. *Results:* Formation of emboli; infarction; heart clot, and sudden death; cerebral softening; the thrombi may become organized, liquefy, soften, become calcified, putrefy, become discolored, or may resolve.

Varieties of thrombus: *Red thrombus*, which originates from blood at rest, such as after ligation of the femoral artery for popliteal aneurysm. It is soft, not laminated, consists of a loose network of fibrin which entangles very many red corpuscles and a few leucocytes; it adheres to the vessel wall and later contracts. *White thrombus*, which originates from circulating blood, such as is found in an aortic aneurysm; it is firmer than the above, it is laminated, it is dense; it is composed chiefly of leucocytes, but red cells are also present, as well as fibrin network and some granular material, probably derived from broken down blood platelets. *Parietal thrombus* is one which adheres to the vessel wall, but only partially occludes the blood-vessel, in opposition to an *obstructive or obliterating thrombus*, which absolutely obstructs the blood channel.

An **EMBOLUS** is a plug in the circulation. The process is called embolism. *Causes:* Thrombi, detached pieces from the heart valves, microorganisms, oil, fat, parasites, pieces of new growths. *Results:* Obstruction to the circulation; infarction, inflammation of blood-vessel; dilatation of blood-vessel.

Infarction is the condition produced by the plugging up of an end artery. It is an area of degeneration and inflammation caused by the presence of an embolus in an artery that has no anastomosis with other arteries. There is a conical shaped area of tissue deprived of nutrition, the apex of this area being toward the interior of the organ, and the base toward the external surface. As a rule the infarct is firmer than the rest of the organ. *Results:* Infarcts may be replaced by connective tissue and scar formation; they may become encapsulated; liquefaction necrosis with cyst formation may occur.

9. A **carcinoma** is a malignant tumor of epithelial origin.

A **sarcoma** is a malignant tumor made up of cells which resemble those found in embryonal connective tissue.

In the *breast*, carcinoma is probably the most frequent malignant tumor; sarcoma is rather infrequent.

In the *liver*, carcinomata are the most common of the tumors found; sarcomata are much less frequent.

In *bone*, sarcoma is especially common; carcinoma is much less frequent.

10. *Osteomyelitis:* "The marrow first becomes red and edematous, then cellular infiltration and proliferation are superadded, and finally collections of pus or diffuse purulent transformation follow. The surrounding bone is involved, becoming more or less infiltrated, softening, and not rarely undergoing necrosis. Small or large sequestra may be formed, or the bone may necrose completely. Periostitis is generally associated, and the tissues around the bone are usually infiltrated

and suffer suppurative or necrotic changes. Hypertrophic changes may occur in the periosteum and superficial layers of bone, causing a bony encasement of central sequestra. In such instances a suppurating sinus, extending from the bone to the surface, usually remains."—(Stengel's *Pathology*.)

11. *Jaundice:* "It seems as if true jaundice were always obstructive in nature, with regurgitation of pigment into the circulation. In obstructive jaundice properly so-called, it is obviously so, for there is an obstruction in the bile channel somewhere between the hepatic lobule and the papilla in the duodenum; there may be congenital narrowing or absence of the main ducts, inflammatory swelling of the walls with narrowing of the lumen (*catarrhal jaundice*), growths or foreign bodies within the passage, new growths outside the passage, pressing upon it, or perhaps even a spasmodic stricture of the duct. With any of these the bile channels are distended, and it is found that ultimately the pigment injects a fine intracellular network of channels, connecting with the bile capillaries. This network surrounds the nucleus of the cell but does not enter it, and if distended, throws back the bile upon the cell, where it is at once absorbed by the lymphatics; and perhaps less rapidly, but surely, the pigment makes its way into the hepatic blood; the latter process is much hastened if rupture of bile ducts should occur. A second way in which jaundice can be caused is by the breaking down of a large number of red corpuscles in the circulation; the liver cells, presumably overloaded, excrete a concentrated inspissated bile by which the fine channels are blocked; the obstruction is not complete, the feces may remain colored, and the jaundice may not be very severe; such a form of jaundice may occur in sepsis, and is evidently *hemohepatogenous* in its nature. Yet another kind of jaundice is found in such states as acute yellow atrophy of the liver, in phosphorus poisoning, and in the infective jaundice of children where the pigment is evidently freed from liver cells during their destruction; it must be remembered, in fact, that whenever many liver cells are destroyed at the same time jaundice may supervene. Finally severe shock or nervous disturbance has been followed by jaundice, a phenomenon which we are not able to explain."—(Adami and McCrae's *Pathology*.)

12. *Cloudy swelling* is a form of degeneration in which the cell protoplasm becomes edematous and opaque.

Atrophy is a decrease in the amount of a tissue owing to diminution in size or number of the histological elements of which it is composed.

Malignancy is the characteristic of certain tumors which have a tendency to destroy life, to recur after removal, to produce cachexia, to cause metastases, and to infiltrate the surrounding tissues.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

NEWER PRACTICAL POINTS IN THE TREATMENT OF TYPHOID FEVER.

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

IN some degree toxemia is present in every case of typhoid fever. The degrees of it are very different. At times, even the end of the second or during the third and fourth weeks of the disease, it has seemed relatively mild. There has not been a high range of temperature, there has been only moderate diarrhea—no internal hemorrhages have occurred, and the nervous phenomena have been relatively slight. We are then somewhat inclined to believe it is our rational treatment which has occasioned this desirable state, or if in the hospital ward there have been numerous mild cases, we might think it was evidence of the character of the epidemic.

Many years ago not a few of our ablest practitioners accepted the facts as reported from the German hospitals of the great success of the Brand treatment, and felt called upon to carry out their doings here. Of course it necessitated three or four able-bodied nurses, men or women, to give the baths properly and as often as they were indicated. In well governed hospitals, however, it could be done and was done. In private practice it was another matter, and only in exceptional cases was it really feasible to give the Brand baths. The expense could not be supported. In addition, place for the nurses in the home was a great difficulty, not to speak of extra meals.

Fortunately, some of us were never convinced that the Brand system should be commended in such a wholesale way. We believed that by sponging the body and limbs with water, or water and alcohol at a temperature from 70° to 80°F. we could reduce the temperature, give tone to the nervous system, and promote the comfort of the patient as far as was essential.

If under this treatment the patient developed bad symptoms, we did not believe they would have surely been prevented by employing the Brand treatment. This conviction was established more firmly in the case of women and of weak, nervous patients and where the baths had not been given early in the disease, say before the expiration of the first week.

It would now seem to me, judging by what I have seen, that the majority of practitioners take this view at the present time. I have always insisted, as far as may be, that patients should drink water freely and often. On the other hand, I have not felt like forcing it upon them and as some do, in very large quantities—even as much as two or three quarts in twenty-four hours.

Of course, when the urine diminishes notably in quantity and perhaps gives evident signs of a low

grade of nephritis, with casts and albumin present on examination, we must try to remedy these symptoms. Then it is we may with great advantage turn to rectal irrigations with the short recurrent tube of Dr. R. C. Kemp.¹ The irrigations may be repeated several times in the twenty-four hours. Very soon the bulk of the urine increases and other symptoms improve. Notably the heart action becomes stronger, the temperature lowers and the patient is less apathetic, or somnolent. Hence we find it easier to feed him sufficiently, with cereal or other broths.

We owe to Dr. Seibert² and to Dr. R. C. Kemp the value of milk-free diet and enteroclysis in typhoid fever. Dr. Kemp³ writes as follows: "I have noted the tympanites and temperature lessened when milk was withheld, and increased when milk was again administered. With milk-free diet my patients have had much less tympanites and the temperatures have run much lower and the disease has run a milder course. In fact by this method, combined with rectal irrigation and the ingestion of large quantities of water, the temperatures have generally kept below 102.5°F., so that friction bath (Brand), or the Nauheim bath could be omitted."

Whenever for one or another reason we find the rectal irrigations are objectionable, as for example, if they annoy or fatigue the patient very much, or if there has been an intestinal hemorrhage in larger or smaller quantity, we shall find in hypodermoclysis a very valuable adjunct to our remedial armamentarium. To secure greatest advantage from it, however, it must be given with care and strict attention to some details in practice.

These should be: To give the subcutaneous injection slowly, at the right temperature, in the proper locality, and not too much at any one time. Of course, before puncturing the skin with the needle it should be properly sterilized and anesthetized. As a rule, the saline fluid is rapidly absorbed and causes very little distress. But this is not always the case, and occasionally the patient complains of the pain caused by the injection. In many instances this drawback is greatly overbalanced by the good results obtained. The pulse is strengthened and the quantity of urine increased. After one or more injections of three to six ounces of fluid the entire aspect of the patient has notably and visibly improved.

It is usually stated that a dose of calomel or other purgative should be given at the beginning of a typhoid attack, and this treatment is considered highly advantageous. Later on we should rely, in the judgment of most writers, upon enemata to move the bowels properly. According to them, when there are pronounced loose and frequent movements, enemata should be stopped.

With these affirmations I am not in complete accord. It seems to me that even at the height of the fever, or during the second, third, and even the fourth weeks, it is desirable to give an occasional

dose of palatable castor oil, or a little purgative water, like Hunyadi. I am quite confident it is beneficial and carries off some of the poison of the disease. I do not believe it increases the danger of either perforation or hemorrhage. Very probably it has, on the contrary, a desirable local effect in cleansing the ulcerated surfaces and carrying away from them much that is infectious and poisonous. Indeed, in one instance I can vividly recall where there had been considerable and repeated hemorrhages from the bowels, a dose of Epsom salts relieved them completely. As the patient was decidedly constipated at the time, I explained the good effect in part at least, by the breaking up of a hard fecal mass which by pressure was causing the ulcerated bloodvessel to continue bleeding. Whether there be constipation or diarrhea, I consider the laxative by the mouth desirable treatment. It should be given at least every two or three days. I do not think that diarrhea should prevent the use of a moderate saline enema every day. It cleanses the lower bowel and aids the passage of the feces from above in a way which to my mind is curative rather than the reverse. In this connection I would refer to a paper I read not long since, by Dr. Robert N. Willson of Philadelphia, entitled "The Decomposition Food Products as Cardiovascular Poisons," and to the following remarks incidental to the effect of gases in typhoid fever. He writes: "Their toxic influence is apparently due to their absorption as such, and to a direct action on the cardiovascular as well as on all the body tissues. I can easily believe, after observing a number of such instances, that the distress in typhoid tympanites is not altogether mechanical, and that it is not entirely due to over-distension and to dislocation of the heart from its normal position. The intestinal gases appear toxic and the toxic influence is the more prompt and serious." Here again the enema is most useful.

Sometimes when the patient is at a low ebb with weak pulse, faint heart action, oliguria, muttering delirium and twitchings, neither saline irrigations of the rectum nor hypodermoclysis seem to answer the indications so well or so rapidly as an intravenous infusion.

The following account taken from Hare⁶ has great value. The best solution is: calcium chloride 0.25, potassium chloride 0.1, sodium chloride 9.0, sterilized water 1000 c.c. "There is now placed upon the market a 'concentrated saline solution' in which the salts just named are dissolved in an ounce of sterile water and placed in a sealed sterile bottle. The contents of one of these vials added to one quart (1000 c.c.) of pure sterile water make a saline fluid ready for instant use. The dry salts, carefully sterilized, are also marketed. The water should be distilled instead of boiled and used as soon after distillation as possible."

To show the value of saline infusion by the vein, I beg to report an unpublished case recently handed me by a distinguished colleague. In addition, I would refer to not a few instances of my own, which will be found in an article of mine published many years since in the *MEDICAL RECORD*.⁷ My colleague's case is briefly as follows: "The only case in which I recall having used intravenous infusion of normal salt solution in typhoid fever was an extreme one—late in its course, high temperature, delirium, and profound intoxication. In this particular instance, the result—for I cannot think it was accidental—was phenomenal. The patient was considered practically moribund, and I had announced the

almost certainty of his speedy death. I think the temperature dropped five degrees in twenty-four hours, following two pints by vein—he was, within that time, entirely free of delirium—his temperature rose but slightly, and he speedily convalesced. I used the agent in this case simply to dilute an extreme intoxication and promote elimination, until his own antagonizing bodies could better act."

A great improvement in the use of saline infusions, and also in Murphy's drip method,⁷ has been inaugurated by the use of the vacuum, or thermos bottle, which the profession owes to Dr. R. C. Kemp.⁸ By the proper employment of this bottle the saline fluid may be kept more easily at the same temperature than it could previously with the use of hot water bag, thermolytes, Elbrecht's apparatus or other contrivance.

During quite a while and in former years transfusion of blood was employed in very critical cases, only to be practically abandoned in view of its difficulties and dangers. During the last few years with a better technique great advances have been made, and not a few great successes may be claimed by this method. A very striking case was reported by Morris Manges⁹ only a few years since, and lately others have also fortunately taken place. Thanks to the great courtesy of a late house physician of St. Luke's Hospital, I shall now report one taken from his notes.

This case ran a typical, severe, uncomplicated course for several weeks. Late in February, 1915, a recrudescence occurred and during this period hemorrhages were frequent and copious and not satisfactorily checked by cold, or subcutaneous injection of whole blood, kindly furnished by a friend. Transfusion was done on Feb. 28 by Dr. Edward Lindeman. He used the indirect method as introduced by himself, employing a battery of 20 c.c. Record syringes and injected 900 c.c. of blood in about fifteen minutes. From this time recovery, while not uneventful, was progressive and the convalescence satisfactory. Of late, I am informed, in one large New York hospital the "citrate method" of Lewisohn¹⁰ has been used very satisfactorily. Several of the cases of typhoid fever, complicated by hemorrhages, have been thus treated.

On the other hand, a well-known expert in blood transfusion writes me as follows: "Some three years ago I employed sodium citrate. I found it toxic and never again employed it. I am opposed to the use of citrate, or any anticoagulant in blood transfusion. It is unnecessary, unscientific, and even dangerous. Several weeks ago an article appeared in the *Journal of the American Medical Association* showing dangers in its use. It is not toxic for all persons."

In the latest article on this subject by Dr. A. Lewisohn,¹¹ entitled "The Citrate Method of Transfusion in Children," the writer reaffirms his confidence in the method. He has now reduced the percentage of the citrate in the blood to transfuse, and considers it quite equal to blood without any such mixture. Indeed, if we may admit the experiments of Dr. J. Spencer Davis¹² to be correct as to conclusions, we should know that "sodium citrate solution mixed with the blood causes it to produce a greater leucocytic response." The citrate may therefore be doubly useful. The non-coagulability of the blood occasioned by it is a matter of common knowledge. A new method of syringe transfusion by Lester J. Unger¹³ has also met with success in men, as it had been already employed with that result in animals.

Personally, I am as yet more in favor of saline than blood transfusion in typhoid fever when either is required. At least this is my judgment unless a proper donor can be secured and immunized, or is already immune,* and the blood has been tested in a laboratory, as to agglutination, or hemolysis with respect to the donee. With both methods it is essential to have a good surgeon do the operation, or at least one who has had some previous experience and is familiar with the technique.

I have seen saline intravenous infusions do good; I have also seen them do harm. More than once death seemed to me to be more immediate and certain by reason of this interference. Previous sterilization of everything involved—patient locally, instruments, surgeon's hands—is imperative. Further, the saline infusion must be made slowly and limited as a rule to 8 or 10 ounces at any one time. The two pints used in the very successful case reported by me, are somewhat unusual, I believe. Among the newer and still undetermined methods of treatment in typhoid fever we should now place that by vaccines.

In the paper by Joblin and Petersen¹⁴ on Bacteriotherapy in Typhoid Fever, "the conclusion is warranted at present that intravenous bacteriotherapy offers a reasonably safe method of treatment in select cases of typhoid fever, but that further efforts should be made to overcome the definite toxic effects which of necessity accompany the injections."

Among these toxic effects we should note specially the sudden and considerable rise of temperature with severe chill, the notable depression of the heart's action, and the increased peristalsis, which may occasion hemorrhages and bring about fatal termination. Apparently, from the observations of McWilliams¹⁵ and others, the duration of the disease is notably lessened and the cessation of a high febrile temperature frequently lasting. The great and sudden rise of temperature following within a short time, usually one to three hours, lasts only a short time. Indeed, at the end of twenty-four hours from the time of the initial injection it has frequently dropped to normal. Several deaths may be directly attributed to this method of treatment. Those who uphold it state that a like objection may be used frequently against any novel or advanced system. As the contraindications and dosage are better understood, such fatalities will probably diminish. The dose now employed ranges from one hundred to two hundred and fifty million bacilli. Various types of vaccine occasion similar changes in the blood picture.

Dr. Austin W. Hollis read a paper before the Medical Association of Greater New York on December 20, 1915, on the value of intravenous injections of vaccines in the treatment of typhoid fever. Dr. Hollis's report from accurate observations in his wards at St. Luke's Hospital, New York, is surely, in some particulars, convincing, although the number of his patients was limited. It is also true, I believe, that no comparisons were made between patients treated with vaccines and those who at the same time were treated by former methods. It may be, therefore, that the results obtained are more favorable than would be really jus-

*A donor who has been immunized, or who is already immune by reason of a previous attack of typhoid fever, is not so essential where the transfusion of blood is done to replace blood lost by repeated hemorrhages, as it is in instances of profound toxemia from typhoid fever.

tified by a close analysis of different treatments of typhoid fever, carried on at the same time with two sets of patients.

It might be added that at the Mount Sinai Hospital, New York, physicians to the institution have not employed intravenous injections of vaccines in the treatment of typhoid fever, because of the poor results hitherto obtained with them. One of the attending staff writes me, December 27, as follows: "They (the physicians) told me that cases so treated have shown very marked toxic symptoms (literature-reports), and for that reason they have not tried this method."

The latest, published article on this subject, is one by Dr. Joseph L. Miller of Chicago,¹⁶ who gives a detailed report of his own and others' work. After reading it carefully, however, I have not been able to glean much that was to me encouraging in this newer treatment of typhoid fever.

CONSTITUTIONAL INFERIORITY;

A SURVEY.

BY HENRY M. FRIEDMAN, M.D., LL.B., LL.M.

NEW YORK.

ACTING ASSISTANT SURGEON, UNITED STATES PUBLIC HEALTH SERVICE.

THE spectacle of the great mass of people who are constitutionally unfitted to take part in our present progress is a painful one to us whether it be from material motives, or from altruistic ones, or from that intangible but still present motive of race pride. Race pride must take the place of the more selfish familial, tribal, or national pride. Race pride is human idealism or unselfishness—yet in a measure very selfish, since it desires to see spring from itself the best. Human inferiority or degeneracy can be ethnic, familial, or personal. Race superiority has, however, always been a changing factor. Races now degenerate, or even entirely effaced, were highly developed ages ago. The very factors which made them disappear are important for the present peoples to bear in mind in order to maintain their own integrity. A high degree of civilization, breeding luxury, excesses of all kinds, and consequent disease and degeneracy—conditions under which no race can long survive—was at the

bottom of the fall of many of the now defunct races.

General Considerations.—In general, the newer races are the best. The older races show a high degree of development, but they have already reached a climax beyond which they cannot go. Old stock is consanguineous and needs new blood to rehabilitate it. Blue blood, so-called, is, for this reason, undesirable. The influx of certain races has had a tendency to raise our physical standards. The factors which militate against the standards of a race are race consanguinity and race mongrelism. In the former breeding is entirely within the confines of a race in the tribal sense. Racial defects become emphasized because no new dominant characters are injected. Yet inbreeding is particularly vicious only when some bad stock happens to be injected into the inbred stock. Then there is caused greater havoc than if there had been no previous inbreeding. In good stock inbreeding may otherwise even be desirable. Mongrelism means the crossing of widely separated and wholly incompatible races. There is really no mixture there, rather only a mere suspension, where every factor of the incompleteness and instability precipitates.

Aboriginal races cannot be included in this discussion since they have not yet quite reached the *man* stage. When attempts are made to develop them they progress up to a very limited degree only, although the rate of development may even be more rapid than in the civilized. It soon, however, ceases entirely. There is a limit to their humanization. Man's civilization, though at present seeming boundless, has brought with it a train of vices, diseases, and defects. Indeed, it is often said with truth that civilization has meant syphilization and degeneration.

Of the five races of mankind we naturally consider the white race the superior one, although other races have had high degrees of civilization ages before that of the white races. Of the European races it is now difficult to say which are the superior. Southern Europe has labored under great disadvantages. It has always played the part of the cockpit in which the best of the races were destroyed, leaving the most inferior to repopulate. Naturally, or as the direct result of the violence of war, there is caused the rapid mixture of widely different peoples, so inimical to stability. Withal, Southern Europe is still the mother of a sort of human genius—the fine arts. It may be that this is exactly the kind of temperament or constitution necessary for its development. Art is emotion translated and depicted. Northern Europeans are of a higher order physically, but because of the greater opportunities for inbreeding they are subject to many individual defects. The fact is that every race has its elements of superiority and inferiority. It cannot be decided what quality or what achievements, or the lack of which, makes a race superior or inferior.

Still less can be said on the superiority or inferiority of individual types. Blondes are said to age sooner, to be more susceptible to adverse environmental conditions than brunets. Sudden and long continued changes of climate seem to effect blonds more seriously than the darker types. The many race and individual types have and will continue to play an important part in the standards of this country.

The term "constitutional inferiority" is comprehensive. Unless this is kept in mind some particular quality will be given too much weight in one's

favor, or another may be the basis for a wholly erroneous judgment. Only after lining up all qualities with their respective weights, *pro* and *contra*, can a general valuation be given an individual, which shall place him into the class of the actually inferior, or only into the class of the theoretically inferior in which all human beings belong because of the natural imperfections of all mankind. No one is perfect or free from taint. In so far as we are all imperfect, so far can the evidences of our imperfections be multiplied until there is no one that cannot be included on some evidence. Even the few successful men of history will not be found to be free from some taint of degeneracy handed down by their ancestry. Constitutional inferiority is degeneration—a defective basis; it is a marked deviation from the normal or standard types. "It is a process of natural dissolution, disintegration, mental, moral, or physical." In order to determine the scope and the nature of this inferiority there is required the aid of all the sciences—the medical, the psychologic, the pedagogic, the philosophic, and the sociologic. In the study of this subject the finding of the perfect is not aimed at—in this mundane sphere that might even be highly undesirable. The normal or the perfect, like the classical type of disease, is for the lecture room only. Practically, it rarely, if ever, occurs.

Constitutional inferiority is relative. It varies in accordance with the standards. The higher the standard the greater the number of those embraced. The greater the requirements of progress the more individuals are found to be of grades too low to keep abreast. They are just a stage below the degree of human evolution. Evolution brings in relief new faculties and powers heretofore required, and betrays those who have not these faculties or powers or in whom they are only defectively developed.

All defectives, no matter in what degree or in what manner, are in those respects inferior in composition or in constitution. In speaking of this condition it will therefore be necessary for the sake of localization, unless desiring to designate generally, to state in what respect—in what faculty or system—and in what degree one is inferior. On the other hand, the human body is so bound up within itself that there can be no element of defect in its composition which does not have a baneful effect upon the whole organism. "The system consists of an agglomeration of organs which hold certain relations to each other and which in their ensemble determine the nature and character of the individual." A defect in one part may bring other parts out of tune and cause a general disharmony in the organism. The subtle conditions of various kinds to which man is heir, and which baffle explanation, are due to some disorder in a very fine or very highly developed part of the general organization.

Constitutional inferiority is the basis of all diseases, all conditions, all predispositions and all susceptibilities. It is predisposition and susceptibility *par excellence*. It is basic pathognomy, without the intervention of which exciting causes are of no avail. It is lessened vitality with the tendency to transmit a like or even a lower degree of development. Without added insults, however, there is a tendency for the organism to return to the prevailing type. Some of the offspring of a degenerate are even over vigorous generally, or only with respect to the inferior condition transmitted, so as

the more quickly to regenerate. This may be the explanation for the presence of the genius or the saint in an otherwise bad family. Yet even with the marked likelihood of subsequent regeneration, there is an appreciable delay, during which time the offspring are sufficiently backward to hamper the progress of this, their species. The human race has risen steadily, some of them, at least, under enormous stimulation, but with the rise there has been the sacrifice of a great many who, trying to emulate the enormous efforts, have, because incapable from constitutional weakness, fallen from exhaustion, to form either themselves the class of degenerates, or to pass these qualities on to their progeny.

It is from the study of man's composition that we are to learn his character, his mental capacity, his physical condition, his resistance or susceptibility to disease, his temperance, his moral and intellectual endowments. Human derelicts live in embryo in the constitutionally inferior. Many latent inferiors never become patent ones because of the intervention of some discipline, correcting influence or benign environment. It is the problem of the day to find out these latents and to supply the very influences which only a few receive by accident. The problem is a human one entirely. In animals the derelict element soon perishes. Only the fittest survive to advance the evolutionary scale of their species. In human beings, however, the artificial or medical selection, so-called, of civilization preserves the weak to transmit the condition and to burden society with their care.

In speaking of any condition, subject, type, etc., the question that at once presents itself is—what does it look like? What is there to take it out of the general and put it into the class of the special, peculiar, or atypical? While we may have a definite mental picture of a particular degenerate, without further pathological data, we are usually very vaguely orientated on the class to which this type belongs. We desire more information, for example, on the type of his head, of other parts of his body, his expression, his reaction, his malformations, his mental capacity, his judgment, his social scale, his education, and the like. In short, the questions that naturally present themselves are the very ones which must be answered before one can determine what constitutes degeneracy.

Physical Degeneracy.—Physical degeneracy or inferiority, while apparently a separate entity, is usually found in conjunction with degeneracy in other elements of the human organization. Wherever there is much moral or mental defect there is an accompanying, if not an underlying physical inferiority. *Mens sana in corpore sano* is more than ever true. Physical degeneracy embraces every atypical variation from general malnutrition and poor physical development to the most minute physical defect which might in any way influence efficiency, typical form, or symmetry, or, which in any way points to a degree of evolution below the average. Pure symmetry of form is not aimed at except from the wholly sentimental or artistic standpoint. The desire for mates of this kind alone is in itself a degenerate sign, since there is then an evident inability to appreciate physical or other qualities other than those entirely superficial. Perfect symmetry of face, with the absence of the facial lines of a thinker, is a face unpuckered or unscarred from the battle of thoughts. The lines of great men's faces are beautiful only to those who can

read the story of the lines, who can speak their language—to others they are mere hieroglyphics. Indeed, when parents speak of their children as beautiful it will be quite in order to ask not merely for their photographs, perhaps well touched up, or for some other peculiar quality, but to inquire for their survey sheets. There would be pictured the real child. The classical features of degeneracy, so-called, are not true, and the schools that held that form and appearance are real indices of the normal and of the degenerate are fast disappearing. Criminal anthropology, not physiognomy, is now the study of tangible physical defects such as rob the system of the benefits of a normal body. No stigma of degeneration is common to any one condition.

In whatever part of the organism we should look we can find certain features, the so-called stigmata of degeneration, which imply a defective basis somewhere. Rarely are they found in a number of places in the same individual. Physical or anatomical stigmata denote a departure from the prevailing type in the direction of lessened complexity—to a type in a cruder state of evolution. Anatomical stigmata are more nearly akin to the normal in some lower type of being, not necessarily a counterpart but merely a leaning toward—a kinship with some phases in common. Often there are left distinct anatomical structures, in a greater or lesser degree of perfection, which conform strictly to parts in the lower animals—the so-called teratomata. They are said to be the useless scaffoldings left in the body after the work of developing the species was completed, or rather left there because the newer being was yet incompleated. The presence of these scaffoldings but reflect upon the unfinished and therefore inferior quality of the individual.

Because there is no human perfection there is none who has not one or more signs of this imperfection, who has not some stigma of degeneration. None of us is as yet perfectly differentiated from our animal ancestors. Stigmata are serious only in proportion as they are profound or as they are numerous. A few stigmata mean nothing. Unless the defects or air holes in a chain are very large or very numerous the strength of the link is not effected. On the contrary, a few hollows may strengthen, on the same principle as the hollow pillar is stronger than the solid one.

The Anatomical Stigmata.—Among anatomical stigmata may be mentioned the various misshaped heads, upper jaw prominence of the face (prognathism), ear deviations (the especially known Darwinian tubercle), prominent orbital arches, drooping eyelids, absence of eyelashes, ocular asymmetry, absence or arrested development of the eyeballs, juvenile cataracts, albinism, flattened or saddle-shaped nose, high arched and narrow palate, malformation or malposition of the teeth, harelip and cleft palate, supernumerary or malformed breasts, supernumerary or absent ribs, specially weak abdominal musculature (hernia), malformation of the extremities, shortening of the lower and lengthening of the upper extremities (monkey-like), polydactylism, syndactylism, extradactylism, large hand-like feet and toes, hypospadias, epispadias, median scrotal fissure, eunuchoidism, hermaphroditism, feminism, masculinism, elongated or movable coccyx, spina bifida, lefthandedness, dwarfism, gigantism, malposition of organs, vestigial organs, etc. In the adult the presence of these stigmata mean little since their import to the individual has already become manifest. In the young their pres-

ence should arouse serious concern, should stimulate search for stigmata in the other systems—the mental or moral organizations, and should turn all efforts to find a path in life in which these defects will cause the least amount of friction to the individual.

Moreover, as general stigmata of degeneration are to be mentioned precocity, premature aging, and a generally atrophic condition. Most lower animals reach maturity at ages earlier than man. Precocity in man is, then, a reversion or atavism. Certain races have this tendency, usually the consanguineous or the widely crossed.

Physiological Degeneracy.—While anatomical stigmata are easily detected on any routine examination, the physiological stigmata act pathologically to the system and come under the scrutiny of the physician in that way. The correction of these difficulties forms a large part of every physician's practice. Of these the diatheses and constitutional diseases are usually hereditary. As in the case of hemophilia there is a very peculiar and specific form of hereditary transmission, that can leave no doubt that one deals with some basic familial defect—the defective basis. Diatheses are sensitizations or susceptibilities or physiological weaknesses of the system, transmitted to and increasing in the future generations, unless previously eradicated or weakened by mixtures with stock which is dominant in this respect. They are anaphylactic susceptibilities in contradistinction to the natural immunities transmitted in superior stocks.

Physiological Stigmata.—Among specific stigmata may be mentioned the thyroid states and other evidences of defects of the internal secretory organs, albinism (the visual effect), color blindness, nystagmus, strabismus, myopia, hyperopia, astigmatism, concentric limitation of the field of vision, deafness, tone deafness, movability of the muscles of the ear, and movability of other usually immobile muscles, ties, stuttering, mutism, tremors, epileptiform movements, merycism, lack of vasomotor control (blushing, blanching, and angioneurotic edema), neuralgias, migraine, cyclic vomiting, hyperesthesias, anesthetics, transient albuminuria, achylia, hemophilia, etc. The physical, together with the physiological stigmata come near being the bases on which nearly all the bodily ills are founded. The robust will usually withstand epidemic disease to the very last, whereas the weak and the defective are the first to succumb. They not only lack the immunizing power of the normal system, but they have the anaphylactic power highly developed.

Mental Degeneracy.—It must be conceded that within certain limits a man can find his niche in life without a great degree of physical perfection. This cannot be said of mental development. The mentally inferior hamper and are hampered everywhere and at all times. At best they can do but the coarser work of life. Because constitutional mental inferiority towers so much above every other form of inferiority the term "constitutional inferiority" has come to refer almost exclusively to mental inferiority. Not all mental inferiors are necessarily wholly inefficient. The inferiority may be of one kind or another, in one mental faculty or another—entirely or only partially. Unless called upon to officiate in an endeavor in which the defective faculty would be called into play, they may do very well. They may even be geniuses in their own spheres. Besides, here also it is not the mere presence of defect, but the number and especially the profundity that

counts. Even the very defective can be trained in faculties in which they are found capable of doing a sufficiently useful work to become self-sustaining. These are still abnormal, however, because, besides supporting themselves, they are unable to contribute anything to society. That is the test of mental normality. There is no standard, for the requirements are being continually raised to meet the advances of progress. The inferior are those who cannot keep pace with that progress. "On the brain depends the rank, usefulness, guidance, and place in society." Yet "there are mentally diseased persons about whom it can be said that they are removed from a clear view and correct perception merely by a shade of color, a slight variation of light." The borderline condition is that "twilight where brain light and darkness, social fitness and unfitness merge into each other." The shades of mentality are so many that even very slight differences in color are very wide apart.

Starting from the broad basis, axiomatic in character, that there is no human perfection we reach the indistinct and ill-defined conditions that merely mark out some people as different from the mass of people—they who are queer, eccentric, atypical, somewhat dull of comprehension; then to the more individual defects that are recognized as pathological but which yet do not necessarily impair the general or a special efficiency; then to defects that are of such a general or particularly profound character that efficiency and usefulness are impaired unless specially trained, and lastly the absolute inferior who must be under constant care and is of no value to himself or to the community. This, then, is the range of mental inferiority. There is a very gentle gradation—never a sharp line of demarkation between the normally imperfect, and the perfectly abnormal.

The study of psychiatry has yielded but a small mass of the definitely inferior. There still remains the task of combing through the large amorphous mass of the subnormal for more definite pathological classifications. The defective is, nevertheless, a far more definite entity than the normal, for it is easier to say who is defective than who is normal. The defect is limited in the lowest by the ament or idiot; the normal have no highest limit. Every advance makes the distance greater. We are mentally inferior to the extent that we stop progressing, and that, no matter how rapid has been our previous rise. This is the nature of the progress of aborigines—the ethnic defectives. We ought to progress in early years, generally; in later years, specially. Specialism or specialists are later year developments. Normally, specialists are not born; they are developed. The born specialists who include infant prodigies, the savant-idiot, and the like, shine only in one faculty to the exclusion of all others. There lies their degeneracy. Where no element in us progresses we degenerate. There is no standing still—no middle course.

In mental inferiority, more than elsewhere, does heredity play an important rôle. Of all the conditions that have a tendency to be visited upon future generations mental degeneracy is the most apparent. Chronic diseases of all kinds, alcohol, drugs, syphilis, arteriosclerosis, immorality, and insanity in the ancestors seem to be converted into mental degeneracy in the offspring. Like all parasites or lower species of less complexity or less differentiated organizations, such individuals are very prolific. The higher the organism, or the more dif-

ferentiated the tissue, the less the power of reproduction or regeneration. Thus while prolificity is the problem in the degenerate, lessened fecundity—race suicide—is the problem in the highly developed.

Mental capacity has nothing to do with education, information, or mere knowledge. "No mind is more poorly trained than one which is crowded with items of information without any inner relation between them." It is not knowledge but intelligence with the ability to think logically which determines mental capacity. The mind craves logic. The ability to think logically is the index of the normal mind. The foundation—the intellect, never changes in quality, but it can be highly polished by education. With a poor foundation it is better for an individual and his offspring that there be no education than a very elaborate one, which it cannot uphold and most soon crumble. On a poor foundation, the more you build, the more elaborate the structure, the greater the ultimate loss. Taking a lesson from the builder, therefore, before starting an education, "borings" in the form of surveys should be made of the ground to find out how much weight, if any, it can stand. Not every ground can stand every weight. Probably the present precocious—the future *præcox*, might never be had there been less education and had the individual been put in a slower environment. The elaborate structure is likely to be precipitated downward with the slightest wind.

Neither heredity alone nor education alone is the sole factor in shaping the mental character of an individual, otherwise the great mass of men who have no opportunity for education would be especially prone to deterioration; and were the hereditary defectives absolutely irreclaimable then all human effort to improve race and conditions would go to waste; and the fallacy that environment and training cannot influence Nature would be a truism. Proper education is a factor. For instance, motor minded individuals for whom the ordinary information cannot be transmitted through the motor paths, must remain defective unless this condition is recognized and provided for by vocational rather than academic education.

The large class of individuals who live in the sub-soil of life, just under extreme adversity but never quite above it, who are incapable of meeting their own particular demands on life, and what is more significant mentally, are not concerned about it, are constitutionally inferior. This is the class of the chronic pauper, the beggar, and the like. No one can be in contact with them even for an inconsiderable time without realizing their mental condition. So large a burden are these on the public that it were perhaps best to keep the chronic pauper in at least as much restraint as the feeble-minded.

There is no sphere of life into which the question of mental capacity does not intrude itself. More and more people, previously classed normal, are now found among the defective. Genius, precocity, eccentricity—all are under scrutiny. "Genius is neurosis," they say, for geniuses are so often found in known defective families. It is explained on the ground that "before final decline in a line there may be a peculiar blazing up of the psychic forces and power; that frequently the degeneration may be associated with a peculiar gift, which would especially pronounce itself within the realms of imagination and emotion, and cause just these phenomena that demand such a hot subsoil—the creative and

the productive arts—to have their homes in these misty regions." Both extremes are found to result from ancestral degeneration—the degenerate pure and simple, and the genius. It is, as it were, that the ancestral condition prevented the complete development of the germinating element in the parent and caused the formation of unfinished progeny. Even mild defect, like mild contagion, may give rise to a severe one in those to whom they transmit.

In mental degeneracy the difficulty of detection is very real since the signs and symptoms are many and varied, intangible and projecting in all conceivable directions, where one must learn to delve and search if one would find. There is nothing apparent to the eye; symptoms are far beneath the skin, and the area of distribution is very large. The tendency to distinct psychoses increases with the degree of the defective basis, with the kind and with the amount of the environmental adversity. There is nothing fixed. The form of psychosis which is considered to be particularly a graft on constitutional inferiority and psychopathic tendencies is dementia *præcox*. There is monideism, a form of temporary specialism, in which there is an inability to apply oneself to more than one subject—an inability to apply oneself to many interests. There is the characteristic self-meditation—the so-called "shut-in" characteristic.

Mental Stigmata.—It is again the profundity and number rather than the mere presence that is significant. Every mental stigma may be the motive force for some irrational or antisocial act. When mental stigmata are found combined with the constitutional psychopathic tendency, that is, with a history of distinct familial psychopathy, they should arouse special concern. Here also do the stigmata prevent contact with the environment, teeming with stimuli for our reception. Stigmata act as insulators to keep us out of the circuit. Some of the stigmata are such slight variations or are present in some yet unknown or invisible organ, yet undifferentiated or unnecessary for this stage of evolution.

Of the mental stigmata, nervous or emotional instability is so general that it is impossible to localize it. Most likely the condition pervades the whole nervous organization. It is usually recognized only after prolonged intercourse. You feel that there is something wrong with the individual, but you can rarely "get the goods" on him, as they say. Hysteria, the neuroses, and neurasthenia are well known examples of weak nervous systems.

Among the more definite mental stigmata may be mentioned the want of harmony, lack of balance, lack of the sense of proportion, disequilibrium of memory, faults of perception, of association of dissociation, of attention, of judgment, of the sense of reality, of foresight, of insight, of reflection, of judgment of memories, of color weight, weight, size, dimension, of initiative, of imagination, of comparison, of constructive or synthetic imagination, of suggestibility, of intelligence, of personality, of will, of consciousness, etc. Sensory stimuli may be poorly transmitted or relayed, and there is not aroused the same train or complexity of thought. There is failure of mental elaboration. Stigmata in one direction may, nevertheless, allow other directions to be fully opened and even overdeveloped. These may even become prodigious—whence the defective prodigies. But they lack initiative and native ability and need guidance. The conditions

enumerated are variations in psychic elements, though not in strictly psychic units. There are, however, many stigmata of a more complex though more appreciable nature, among which may be mentioned the so-called, though not actual, insanity of doubt, echolalia or irresistible repetition, aboulia or destruction of will power, coprolalia or the tendency to obscenity, pyrophobia or fear of fire, agoraphobia or the fear of open places, and as an antonym the fear of closed places, dipsomania or the periodic tendency to drinking bouts, the drug habits, salomania or the food craze and gluttony, irresistible impulse to homicide or suicide, sexual perversion, aritmania or the desire to be counting continually, onomatomania or the irresistible and incessant search for certain words, mania for certain sports, plays, etc., beyond all reason and endurance—they who never know when they have enough and the like. To this list may be added the subnormal people with the ever-changing fads and crazes, the filias—like zoophilia, the undue solicitude for animals—and the cranks. The latter are often idealists who have divided and subdivided their ideas, their reasons and their emotions until they become amorphous bodies without form, without cohesion and impossible of organization into anything of definite value. It is they who have an exaggerated sensibility and irritability, evidences of their emotional instability, and who are so likely to be guilty of acts of passion.

It must be now apparent what wide latitude of distribution these stigmata enjoy and how difficult it is to make one distinctly mentally defective for being subnormal in one or more of these psychic elements or complexes. The emotionally unstable give the most trouble. They are the ones who get delirium with the slightest disorder, get frequent fainting, crying, or laughing spells, easily lose temper, tear their hair, tremble, and are in other ways quite impossible. They are non-resistant to stimuli. On the other hand, there are others of like instability who are over resistant to stimuli; they are quiet and backward, have no sense of humor and easily become offended. They are of a class one is always at a loss how to treat.

Though surcharged with emotion, the dreamers and the imaginative ones cannot always be justly placed among the inferior. Imagination is a very important part of the normal psyche. If disordered we have the delusion, the cardinal symptom in insanity. A delusion is an infirmity of the imagination. Or, together with the hallucination and the illusion, it may be said to be an acromegaly or gigantism of this part of the psyche. The weak-minded do not distinguish between the unreality of imagination and the reality of fact. The weak-minded dreamer makes no use of his imaginative powers; he indulges in its pleasures, abuses them, and goes into a sort of mental debauch—a sort of mental masturbation. Normal imagination is the planner, the inventor, the designer of the mind. Philosophical speculations are entirely creatures of the imagination. Without imagination one can be no more than "a hewer of wood and a drawer of water,"—can do nothing constructive. The design of many of the substantial structures in every endeavor found origin in the imagination. In one with this great power intricately developed and finely functioning, a break somewhere might produce some very bizarre results in themselves inexplicable, but well illustrated in the inexplicable nature of delusions. Analogous results may be

caused by disorders in any of the elements of the psyche. Moreover, every psychic stimulation, after producing the impression, leaves a less vivid one in the mind perhaps for future reference, subconscious, however. It is the association or agglomeration and exaggeration of these many less vivid subconscious impressions which are causative of the many peculiar dream states in health or disease. In disease there is the lack of the inner judgment of the present value of these impressions; in sleep there is, of course, the suspension of the power of judgment.

Foresight, insight, judgment, and memory are the cardinal elements of normality. Of these memory is perhaps the greatest faculty and the one to show defect or disorder first. There are as many memories as there are brain territories accepting outside stimulation. Memory is the key to the whole intellectual life. Nevertheless, many inferiors have remarkable memories, but little power of associating them, hence lacking real intelligence or consciousness.

Moral Inferiority.—The criminal and other delinquents have long been recognized as separate social entities, but it is only recently that pathological significance has been ascribed to their personality or to their acts. Their condition is due to a peculiar mental composition which does not allow them to keep pace with the advance of the moral code of their community—"a control of action in conformity with the idea of the good of all." It is altruistic comprehension. Moreover, this peculiar constitution is so often found accompanied by distinct mental and physical defects that one cannot help being confronted with the conviction that there is at least a relationship between them, somatic in nature. Body, mind, and morals seem to me an inseparable trio wherein the free will, the responsible ego, has no place. Moral control and intellect are both complex brain processes, often apparently, though not always, interlocked. Of whatever nature, however, loss of moral control is a brain enfeeblement, even though other mental combinations, as for example, memory, orientation, etc., may be quite normal. Gross moral lesions are no more visible than gross mental lesions. Neither have yet been localized. Still, as reflecting on the relation between mental and moral deficiencies, it is found that criminals are especially lacking in the power of attention. There is, indeed, a primary instability of attention. They do not pay attention to anything long enough to acquire lasting action. Hence they are inconsistent and unreliable. One can never tell what they are going to do or how they are going to react. There is particularly a lack of logic, coherence, and continuity. They are vacillating, petty, and obstinate.

The criminal is often compared to the savage. Morally, he is a savage, and very much untamed. The chronic pauper and other dependent classes—these poor who are always with us—are, on the contrary, tame savages. Both are parasites incompetent to make their own way. Criminals suffer from an atrophy of the moral sense; the feeble-minded suffer from an atrophy of the intellectual sense or power. Criminals are erroneously classed as the born and as the acquired. If criminality is constitutional inferiority, then all criminals are born criminals, although the disorder may not be aroused in some till later in life. Indeed, not all hereditary qualities to which man is heir appear at birth. They keep coming out during the entire

period of life, some later, some sooner. Some come out in the future lives—that is, of subsequent generations. That accounts for hereditary qualities apparently skipping some generations.

Lack of moral control revolves around defects of cognitive or conscious relation to the environment—defect of moral consciousness, of the sentiments of pity and probity, of inhibitory volition, of reflection and consideration. The secret of morality is the power of inhibition of reflex volition. During adolescence this power is sorely tried and, if lost, spells disaster to the moral constitution.

Moral Stigmata.—In general they have inferior resistance to temptation, want of forethought as to the consequences of an act, and feeble powers of concentration, attention, and remorse. Specifically, they include passionateness, spitefulness, hate, mischievousness, destructiveness, bad habits in general, drug and alcohol addiction, cruelty, brutality, inhumanity, profligacy, licentiousness and libertine habits, lack of modesty, tendency to sex violence, and perversions, sodomy, incest and exhibitionism, vile-ness, loathsomeness, trickery, meanness, villainy, covetousness, cowardice, egotism, vanity, laziness, indolence, listlessness, dilatoriness, pomposity, jealousy, envy, frivolity, giddiness, silliness, wastefulness, filthiness, untruthfulness, etc. Given any of these evidences of a defective moral basis and an opportunity as well as improper restraints, and the anti-social act is very likely to be brought into being.

However, the emphasis must again be put on the profundity of the stigma rather than on the mere presence of it. For example, untruthfulness in a child is often no more than a misinterpretation of the source of a concept—whether from outside fact or inside imagination. The child has at this period usually more imagination than experience. He takes the imagination for the fact. He really lies truthfully. Besides, the test of an untruth is the injury it does or conceals. Otherwise, there are many lies that are “white”—truths, and many truths that are lies.

There must not be left out of the criminal class those parasites on a larger scale, those engaged in business piracy. If they lack the anthropometric or physiognomonic composition of the lower class criminal they do so only because these are hidden behind the polish of their luxurious surroundings. When deprived of wealth and station they soon drop to their true level.

Criminologists are still at variance with regard to criminal responsibility. Legally, one is responsible for his act who knows the nature of it, and that it is wrong. The irresistible impulse to crime has no recognition in law. In the broader sense any constitution tending to make of one a criminal is irresistible as to the owner of that constitution. Nevertheless, a criminal is freed from responsibility only when his act is due to pathological changes in him such as insanity, epilepsy, feeble-mindedness, and the like. Yet it seems that on the same ground of pathological change could be justly included instances in which there is a family history of criminality, insanity, alcoholism, syphilis, etc. These conditions import a pathological condition in the germ and therefore in the individual.

It is obviously impossible to say from appearances who is a criminal, at least before the commission of an antisocial act. The stigmata are suspicious but not convincing. The value given previously by criminologists to appearance and physical stigmata

must be very much discounted. Morality may have as much expression in the face as intellectuality. Neither is definite. The face in the criminal may be like “clear eyes, but yet sightless.” The criminal physiognomy is not a palpable reality, but a “synthetic expression,” an “ensemble of traits,” existing in no single individual, perceived only by the mind, and never appearing in the entirety before the eyes. As a creature of constructive imagination it is quite real. Unless strongly inhibited the muscles of expression were purposed to feature reflexly the “workings” of the mind. In constitution, however, criminals are usually underweight, undersized, undernourished, with poor musculature and poor intellectual attainments, even lacking the education of their station and usually having had no vocational training. Their surroundings are usually of the lowest; they are poorly sheltered, poorly clothed, and poorly fed.

Reconstruction.—All discussion of these conditions is of no value unless it includes at the same time the problem of prevention. It is obvious that constitutional inferiority being in the germ—in the natural composition—of the individual, cannot be cured. Nature's failure may range from complete failure to negligible defects, and it is the province of science to find, weigh, and measure these defects and provide against them. In the ideal the whole tribe of these defectives would be anticipated by the prevention of diseases in general and of breeding by the defective. Excess and disease eliminated in the ancestor, constitutional inferiority becomes a negligible factor in the offspring. More practically, it means the comprehension of the nature, latitude, and distribution of the condition—in the very young, in the school child, in the juvenile delinquent, in the pauper and all others. Physical defects must be corrected when possible, and when not possible training should be intensively along the remaining patent lines. Physiological defects must be treated. Training must be provided for the feeble-minded so that he may be self-sustaining. For those that cannot be so trained proper custodial care is necessary. The criminal may be reclaimed if he can follow reason, if his inhibitory powers are not too weak, and if he can be removed from temptation. The teachers must be of a high order, not merely exponents of the three R's. They should be psychologists, students of child welfare, of child hygiene, and of child life in general. They should be able to apply mental or moral orthopedics. There should be individual training and education, not the same kind and amount forced on every child whether capable of absorbing it or not. The yearly expenditure for education in every community is enormous. How much of it is wasted in trying to put a high value education into a low value mind! Delineation of mental capacity before commencement of education would stop a great deal of this wastage.

With respect to the psychoses it is the aim of the psychiatrist to remove from the defective base the burden bearing the individual under. For the psychoanalysts this cloud takes the form of an injury to the sex organization. For them no emotion, no passion, no sacrifice, no nobility of action, no high motive, is other than a sign of weakness linked with a morbid sex base. It is the belief of this school that the explaining away of this mental cloud will effect a cure.

The methods for detecting even gross defects are still crude. They can, if at all, reveal only the

conspicuously unfit. What is needed is a scheme or method of appraisal which will at once be uniform with regard to latitude and will apply to all classes of individuals. The school system, for example, should have complete records or surveys of all its pupils. No court should take action on a delinquent until after a survey with its digest has been submitted. All public dependents should be similarly surveyed. In the school system surveys should be taken from year to year or from class to class in order to apprehend defects that may be acquired or of late appearance. "Eternal vigilance is the price of safety."

The Survey.—The survey here appended begins with the information necessary to identify the individual—the name, age, place of birth, nationality, race, and the race and nationality of the parents. The place of birth and the nativity of the subject requires comment. It is not so much the actual place of birth as the place of conception that should determine nativity. If there are any personal characteristics derived from mere nativity they will be determined rather by the prenatal, conception and postnatal influences. If one has native characteristics because born, say, a month or even five years before the parents have emigrated to a given place, he will have them even if born a month or five years after their emigration.

The body of the survey outlines the scope of the examination with space for noting the results under each heading. If there are significant details the item requiring the detail, and the enclosure number giving it, should be noted in the column appropriated for that purpose. The survey is divided into sections, one for each topic—for history, for general impressions, for anthropometric measurements, for physical examination, for sensory examination, for speech, for stigmata of degeneration, and for the mental examination.

History.—Here are embraced the ethnic, familial and personal histories. Notation on the quality of the stock should be made only after careful inquiry relative to the stock maturity purity, longevity, etc. Environment includes climatic and geographical conditions and mode of living. Disease predispositions must include all conditions to which the race, family, or individual is heir, but especially those which have a tendency to be hereditary or to leave the system sensitive to like diseases.

The General Impression.—To the experienced observer the items in this section almost tell the whole story of the constitution of the subject of the examination.

Anthropometric Measurements.—These are extremely important, especially because from them is determined the approximate physical or developmental (actual) age of the subject. The chronological age tells only the time one is *in esse*. The rate and speed of development of persons of the same chronological age are rarely alike. The most developed are certainly not of the same actual ages as the least. The younger physically are usually younger mentally, and accordingly less should be required of them. They should be judged, educated and placed according to this physico-mental age. Only the particularly significant physical measurements need be taken. Height and weight are very important indices of the subject's development and health. The head measurements must include at least the circumference, length, width, and height as well as the cephalic index. The important index is that one bearing a relation between the maxi-

mum transverse diameter and the maximum longitudinal. It is found by multiplying the lesser of the two diameters by 100 and dividing the result by the greater. This index is normal when between 70 and 90. Short heads are said to be brachycephalic, long heads dolichocephalic. There are, however, many subtypes belonging to either class. Microcephalic and macrocephalic heads are respectively the idiot's and the hydrocephalic's heads. The width of the face, though often varying with the race type, is of no particular significance here. There are two types of face, the orthognathic and the prognathic. The former is the straight or civilized face type; the latter is the upper jaw protrusion type exemplified in the aborigines. Width of shoulders, chest circumference, together with the width, depth, and air capacity in cubic centimeters must be noted. The chest types include the rickety, funnel, and pigeon-shaped as well as the barrel or emphysematous. For ready reference the standard measurements should be noted on the survey sheet under the actual measurements. This will facilitate the ready determination of the approximate physical age—which should be noted in the appropriate column.

Physical Examination.—This must be very complete if it is to be of value. Only the digested results should be noted under headings, but every variation from the normal must be fully detailed in appended notes. Where there are remediable conditions, the fact with the remedy and the prognosis should be noted under therapeutic prognosis. Under connective tissues is included the skin, bones, joints, and muscles. The alimentary system must give especial prominence to the condition of the teeth, their condition having such a marked effect on health. Examination of feces is not a superfluity. With the presence and the effect of the commoner worn diseases every one is familiar. The effect of the hookworm on the physical, mental, and moral constitutions is now realized. "Lazy-man's disease" is an appropriate descriptive term for it. Hookworm is particularly common among the "poor whites" of the South, among the West Indian negroes, among the Hindus, and among the Southern Italians. In the examination of the respiratory system the presence of adenoid overgrowth and obstruction of the nasal passages must receive special attention. Obstruction to the respiratory passages has a very baneful effect on the appearance and on the mental condition of a child. "Criminals" and "feeble-minded" are often cured by remedying the obstruction. In the examination of the vascular system neither the Wassermann test nor the manometric determinations must be excluded. Gland diseases or disturbances, whether those concerned with the internal or external secretions, must receive full weight. The importance of the nervous system compels a very searching inquiry into the organic conditions of the brain, cranial nerves, spinal cord, spinal nerves, the ganglia, the sympathetic systems, as well as the functional nervous diseases—the neuroses. In the genitourinary system special consideration must be given genital irritations as from phimosis, paraphimosis and the like, because of the bearing on the child's general attentiveness, its sexual habits, and even its moral habits.

Sensory Examination.—The sensory apparatus receives separate consideration because of its great importance in relation to the mental condition. It is through the agency of the special senses that

XIX	174	62.80	190.5	157	125	549	81							

all the stimuli to the brain must come. A defective or nonpatent sense will impede the development of the brain. Hearing, vision, smell, taste, and touch—all play important parts. Sensibility to pain is diminished in the mentally and morally inferior, as it is in the aboriginal races. Here the determination of the therapeutic prognosis is particularly important.

Speech.—Defects in the power of speech, or the absence of it, must be thoroughly gone into for possible remedy, or, where not amenable, for the possibilities of training and education.

Stigmata of Degeneration.—These have already been enumerated. The mental and moral stigmata can only be determined on searching inquiry into the history, habits, tendencies, addictions, social and moral surroundings, temperament, etc. There might even be moral tests as there are mental—tests of the moral conception. There would many “bright” criminals be found wanting.

Mental Examination.—The survey of the mental faculties is divided into two large headings, the psychic analysis and the tests confirmatory of this analysis. The latter is again subdivided into the mental measurement tests of Binet and Simon—applicable particularly to school children, the puzzle tests, and lastly, as confirmatory of these rather abstract tests, the analysis of the educational application in the various elementary branches.

In this examination one comes into actual—inner mental—contact with the individual almost for the first time. To do this there must be a descending, a putting—oneself in the subject’s place. His confidence must be gained, otherwise this particular subject had better be turned over to one who can gain his confidence. Wherever possible, explain the purpose of the test in order that there may be an interest aroused in its evolution. Give plenty of time to think. In fact, urge it—except, of course, where time is the essence of the test. The ability to think sufficiently is what one is after. That is, after all, the supreme test of mental efficiency. Each examiner must formulate his own test questions. It matters not what is asked—or how—so long as it brings out the points desired. Much must be left to the discretion of the medical examiner. That is why he is an examiner. He must have latitude in the nature, but especially in the manner of the examination. Simpler tests or questions must be submitted first. The more difficult ones will be answered more readily by working up to them than otherwise. Initial success encourages and stimulates; initial failure confuses, frightens and discourages. Hasty conclusions are not to be drawn. Nothing is to be taken for granted. Try

everything out fully—that makes for the scientific disposition.

While appearance, impression, and expression of the subject during the examination are often valuable aids to a determination, though convincing for the examiner they must not be convicting for the subject. Watching the methods of procedure in doing a test gives the examiner valuable information. The subject’s expression is usually the meter of the mind’s activity and equilibrium.

The psychic analysis is intended to be only a practical one and without technical organization or consistency. The principal elements are enumerated in the survey sheet. By psychic senses is here meant what might be called the “unspecial senses”—the sense of reality, of personality, of proportion, of the value of life, the muscular sense, etc. The affective sentiments or senses mean the sense of love, pity, honor, loyalty, etc.

The Binet tests and modifications are methods of measuring mental age computed from certain standards already established with average children. If a child of eight does only the tests that are done by the average six-year-old child, he is mentally only six years old. On the other hand this same eight-year-old child may be only six years old physically, and hence on this criterion ought to be normal. In these tests scoring methods deduct fractional credits for failure in some of the tests of a given mental year, or add to it if the child does some of the tests of a higher year. A child may fail in some of the lower and yet do some of the higher and thus the failures and the merits neutralize each other. Moreover, a child may be much older mentally than he is chronologically or physically.

The puzzle confirmatory tests are the outgrowths of the inventive genius of many observers in their quest for more accurate means of determining this most difficult of entities—mental capacity. Most of the tests here referred to were devised by Drs. Gwyn, Mullan, Knox, Kempf, and Loughrin of the United States Public Health Service. The others by Drs. Healy and Fernald of Chicago and the modification of the Seguin Form Board by Dr. Goddard of Vineland, N. J.* These tests have an especial value in illiterates, those who possess little of the verbal refinements of language and the purely motor minded. The tests are in most instances graded for ages and time of execution. These tests are not absolute, nor are they the only ones devised. Every observer of large experience will be impelled to devise his own tests as he does his

*For description and photographs, see Knox, Howard A.: *Lancet-Clinic*, May 1, 1915.

own questions. Defectives may learn or be taught how to execute these tests in the same way that an animal will learn to unlatch a door—reflexly. It does not mean the recovery of such an individual since his own judgment and native ability are the faculties in the balance not his memories or reflex powers. Teaching therefore renders the particular test useless and consequently restricts the range of the test by so much.

In part, the educational analysis must be an inquiry into the history, attendance, behavior, attention, capacity, etc., as well as ability and defect in the various educational units. Where there has been no education this method of confirmation cannot be used and one must confine himself to the Binet, but especially to the puzzle tests. Illiteracy is, however, a sign of defectiveness only when the individual comes from a literate family or environment.

Children may be defective in only one or more of these educational branches, due in all probability to some defect or lack of co-ordination in the psychic elements that govern the acquisition of these faculties. Some are supremely apt in some and very defective in others. An early enough survey will decide where there are gross defects and will counsel energies to be directed elsewhere. Some children are particularly apt in manual training or the domestic sciences. They are usually the motor minded. These should receive this instead of the academic training. The value of determining the child's natural bent or vocational leanings is very important. Handwriting, like other manual expressions—the artist's, for example—is somewhat an expression of constitution, although of questionable value in judging character. A child's play leanings and love should be carefully searched. It is frequently an index of his moral as well as mental leanings.

While the result placed under each subheading in a section is a digest of that heading, the digest of the whole section should be made and placed under the column, valuation or significant feature. Thus, one can quickly look down this column and see valuations for history, general impressions, anthropometric examinations, physical examination, sensory examination, speech, stigmata of degeneration and, finally, mental examination.

Conclusion.—In conclusion it must be said that the value of the survey to the teacher, the social worker, the judicial officer, and others depends upon the knowledge that the conclusions were drawn by the physician examining the individual himself. The examination must not be relegated to lay or other subordinates, unless actually working in common, otherwise the physician credited with making determinations might well hire a sufficient number of them, sit in his office, receive the survey sheets, and make determinations without ever seeing a subject.

351 EAST FORTY-SETH STREET.

Methylene Blue in Facial Erysipelas.—Nobécourt recommends the application of a 5 per cent. aqueous solution of methylene blue in the treatment of erysipelas of the face. The solution is painted over the affected area and for a distance of about half an inch from it on the apparently healthy skin, and the application is renewed night and morning. This method of treatment is claimed to be extremely satisfactory, a cure usually being obtained within two or three days.—*Société Médicale des Hôpitaux.*

PHYSICIAN, KNOW THYSELF.*

BY ANDREW MACFARLANE, M.D.

ALBANY, N. Y.

"Life is not only for work: it is for one's self and one's friends."

THE physician who purchases his first automobile anticipates with joy the speed and ease with which he can reach his patients, even when at a great distance, and looks forward to the hours of leisure thereby gained either for reading, diversion with his family or additional time for the further working out of the problems of medical practice.

Alas! he reckons without his host and soon learns to his cost that he has simply added to his troubles and expenses and increased his perplexities in addition to his vocabulary of profanity.

He starts out and finds his car begins at once to heat up, then after a time he remembers he has not put in any water; he comes to a sudden stop at times far from home, and after destroying his chances for heaven, he learns that the gasoline tank is empty; the motor begins to skip and he wonders in a state of daze what has now happened; the car is without power in spite of a large consumption of gasoline and some good Samaritan tells him to look at his spark plugs. However, after a year or two when he has found out to his cost that his car is not entirely fool-proof, he learns to anticipate its needs and thus prevent his troubles.

He now looks after the supply of water; the quantity of gasoline; the need of oil; the condition of the grease cups and every six months or, at the longest, every year, has his car taken down, the parts thoroughly examined, defective parts replaced and all completely cleaned and reassembled in good condition. He has at last discovered that the life and efficiency of a car depend upon its care. Motoring now becomes really a joy and he goes forth each day with a certainty that he will get there.

The machine we all have to work with, our body, though much more fool-proof than any machine ever made by man, can still be so neglected, abused and overworked that it shows the effect of wear and tear before its time and then is able to do its work only imperfectly or finally completely breaks down and is of no further use.

There is no more creditable chapter in history than that describing how the medical profession has fought and successfully annihilated the many scourges which even within our ken, destroyed each year hundreds of thousands of victims; smallpox, malaria, yellow fever, typhus fever, cholera, diphtheria, and typhoid need only be mentioned to this audience to emphasize this fact.

The community which to-day permitted any of these diseases to gain headway would be immediately treated as a municipal leper, avoided by other communities, and would be controlled, if necessary, by the police regulation of the State, as unfit to care for itself until self-purified.

In spite of this splendid showing of preventive medicine, there is still a greater battle to fight, a more stealthy opponent to overcome, and a grander victory to attain. Vital statistics show a most creditable reduction in mortality and a very remarkable increase in the duration of life. This, however, has only been in those diseases vigorously combated by hygienic measures. The percentage

*An address delivered by invitatio nat the annual meeting of the Warren County, N. Y. Medical Society, at Glens Falls, N. Y., on October 13th, 1915.

of decrease of morbidity has been an index of the efficiency of the methods employed and not of the possibility of attainable results. In twenty-two years (1890-1912) the mortality of typhoid fever has shown a decrease of 65.2 per cent., almost two-thirds, and pulmonary tuberculosis of 48.9 per cent., almost one-half in the United States. If a community should show no decrease in the incidence of these diseases, the inference would be inevitable and the cause self-evident.

If we pursue this subject a little further, however, our mortality results are not so gratifying to

The Death Rate at all Ages is Decreasing in England and Sweden
The Death Rate under 45 is Decreasing in the United States BUT
The Death Rate over 45 is steadily Increasing in the United States
We should do as well as England and Sweden

The increasing diseases are Cancer and Diseases of the Brain and Kidneys and above all of the Heart and Blood Vessels

our national record or personal pride. While in England, Norway, and Sweden the mortality from degenerative diseases; i.e., diseases of the heart, blood vessels, and kidneys, the results of the terrific stress, strain and worry of modern life, is practically stationary; in the United States the morbidity from these same diseases has increased with leaps and bounds. In 1880 it was 21.1 per 10,000 population; in 1890, 27.8; in 1900, 33.3; in 1910, 38.7 per 10,000 population.

This rate is 50 per cent more than that of England and Norway to-day and almost double what it

was thirty years ago in the United States; i.e., 150,-000 unnecessary deaths and probably 300,000 unnecessary invalids per year in this rich and prosperous country. This is well illustrated by 8 charts issued by N. Y. State Department of Health. In ten years among 5,000,000 working people, the death rate has increased as follows: Apoplexy and diseases of the nervous system, 19 per cent.; diseases of the heart, 29 per cent.; diseases of the kidneys and urinary system, 43 per cent.; diseases of the liver and digestion, 34 per cent.

These deaths, too, are at the most efficient period of life and affect especially, and to a greater extent, our most valuable citizens—not the farm laborers or city workers, but the professional men and those engaged in the larger affairs of the world; the so-called captains of industry.

Can anyone estimate the loss by the probably avoidable early death of strong, forceful, active men in our respective communities. They have been cut down when their power for good was at its highest point and their work still far from completed.

Suppose the farmers found that the mortality of their milch cows, their pigs and their horses had doubled in the last thirty years, and that, too, at an age when they had reached their greatest value, would anything be done about it? Would they lie down supinely, do nothing and await more or less philosophically their unnecessary and useless loss?

This condition has an especial significance for the physician, because the strain, worry, anxiety, overwork and exposure of medical life are the factors which especially induce these degenerative diseases.

I know of no more pathetic index of the strain of medical practice than the number of suicides and fatal accidents to physicians. Frequent accidents suggest at least impaired judgment. In 1912 there were 36 suicides and 90 fatal accidents; in 1913, 43 suicides and 101 fatal accidents; in 1914, 27 suicides and 111 fatal accidents—a truly sorry recital; and more than that, it is probably fair to assume that these statistics are far below the actual occurrences.

These poor devils were often more sinned against than sinning. If the rest of us have been more fortunate in resisting these strains, may they not have left penalties upon our myocardia, arteries, or kidneys which must be paid by less efficiency or an earlier death.

From the columns of the *Journal of the American Medical Association*, the following data were collated:

Year	Cerebral Hemorrhage	Heart Disease*	Kidney Disease	Circulatory Diseases†	Unrecorded Causes
1912....	219 = 14.4 %	238 = 15.88 %	138 = 9.0 %	33 = 2.1 %	593 = 38.76 %
1913....	195 = 10.88 %	262 = 14.62 %	140 = 7.8 %	36 = 2.0 %	404 = 22.49 %
1914....	185 = 10.5 %	257 = 14.5 %	108 = 6.0 %	29 = 1.6 %	455 = 24.6 %

There is nothing more discouraging than the

attempt to draw deductions from mortality statistics. In spite of the vast sum of money spent by the United States in the last census, the statistics are practically worthless. Even the data above given have little value, because of the large number of unrecorded causes of death. It would seem as if such a powerful organization as the American Medical Association should set a better example in its mortality statistics.

This great discrepancy between our control of the acute contagious diseases and the lamentable lack of control of the chronic degenerative conditions is partly explainable.

The acute diseases are lightning-like in their onset, rapid and evidently serious in their development, their etiology is well understood and comparatively easily determined, and their contagiousness makes them highly dangerous to the community. It becomes, therefore, the province of the community to combat them and to protect her citizens as it would fight any conflagration.

The chronic degenerative diseases are insidious in their onset, "like thieves in the night," slow and apparently unimportant in their development, their etiology is obscure, complicated, and often impossible to determine accurately and they are absolutely without direct danger to the community. They are in every sense of the word, purely personal—not the subject of direct communal control, but of education and of individual action, *i.e.* of the physician.

That the health of a vast number of people is often seriously affected by such degenerative diseases without a realization upon their part of their condition, is a well-known fact. An insurance company a few years ago offered their policy holders free medical examinations once a year; 2500 with an average age of 46 accepted this service. Forty per cent were found to have some impairment of health, mostly of the heart, blood vessels and kidneys. Of these almost half, or 500 persons were not aware of this impairment. As a result of this knowledge and the ensuing care resulting therefrom, it was found after four years that the mortality was only 50 per cent. of the expected morbidity for these cases. The following results were obtained by the life extension institute in the examination of the employees of commercial houses, banks, etc.:

Fifty per cent. were found to be sufficiently seriously affected to be referred to physicians for treatment.

Organic heart disease	5 38%
Arteriosclerosis (thickened arteries)	13 10%
High or low blood pressure	25 81%
Urinary—albumin, sugar, casts	35 63%
Combined disturbance of circulation and kidneys	12 77%
Other lesions	7.31%

This finding, though at first astounding, is on further thought easily understandable. The man who dies between 50-60 from kidney, cardiac or arterial diseases has probably been developing for many years an impaired condition of those organs before the final catastrophe occurred.

This subject has been one about which I have thought much for some years past, but had never before put into concrete form. It has, however, also been the subject of thought of others and there was organized as a result The Life Extension Institute in New York City. The service of this institute consists of health examinations to detect disease in its early stages when it can be checked or cured and of an educational campaign to in-

crease physical efficiency by promoting healthful living and protection against disease. It deals solely with prevention. Treatment is left to the family physician.

This institute is largely philanthropic and has in its directorate and reference board men of eminence as Ex-President Taft, Prof. Fisher of Yale, Drs. Fisk, Gorgas, Blue, Wiley, Blumer, Edsall, Vaughan, Chittenden, Welch, and many others. It seeks contracts with life insurance companies and commercial organizations to examine policy holders and employees in addition to making examinations for individuals. Whether this institute is meeting with the success its objects deserve, I do not know, but I do believe that the only way it can accomplish in large measure the beneficent results which are possible, is by securing the co-operation and support of the entire medical profession.

If medical examinations to detect diseases in their incipency have any value whatever, then the physician should be the first to recognize that fact and at once make use of this knowledge and the opportunity presented.

If a physician is to become a true teacher of health, he must practice what he preaches. He cannot succeed in controlling drug habits or alcoholism if he himself is addicted to these habits. He cannot fight patent medicines and quacks if he uses them and their methods himself. He cannot successfully oppose the social evil unless his own reputation is above suspicion. If he preaches effectively high standards of right living and hygiene, he must exemplify that standard in his own life. He cannot induce his patients to diet or take exercise if he is addicted to the flesh pots and the easy life. Example must be added to precept to secure the best result.

Therefore, to make personal prevention of the chronic degenerative diseases a success, the physician must himself adopt it. The layman naturally looks to his family physician for guidance on matters of health and hygiene. If the doctor does not value personal prevention highly enough to make use of it, when at no personal cost to himself, then the layman has no confidence in the proposition or loses respect for his medical adviser.

If this sinful and useless waste of human life, almost worse than this horrible war, is to cease, then the physician himself must take the initiative, as he has done in all life-saving propaganda and by example prove to the incredulous world its worth.

He will thereby be the gainer, not alone in the personal satisfaction from the accomplishment of a splendid work for humanity, but selfishly by increased personal efficiency and longevity, with the thereby added income. The physician is the only professional man whose income not only ceases during his illness, but may as a result of such illness, be seriously impaired for all time thereafter.

Casper, a German statistician, has shown that the number living at the age of 70 of a hundred people in any calling would markedly vary: of clergymen, 42; of agriculturists, 40; of merchants, 35; of soldiers, 32; of lawyers, 29; of actors, 28; of teachers, 27; of physicians, 24.

Then, too, the prolongation of the life of his patients would be an added asset. The only patients who are of value to a physician are the living ones. Just as soon as a patient dies, that source of income immediately ceases. This would result not merely in a quantitative increase in years, but in a quali-

tative improvement in the physical, mental and moral faculties. It would raise the standard of health, increase the number of people enjoying this blessing, reduce suffering, misery and all the attendant evils, physical, mental and moral, dependent upon ill health thus promoting the joy of living and developing a sensible efficiency. It would in great measure solve the problems of cancer, tuberculosis, and the venereal diseases. This would mean that we would seek to keep people well instead of trying to perform impossible tasks on worn out minds and broken down bodies.

Suppose that all the physicians of a community should agree to have themselves thoroughly examined at least once a year, and to keep a careful record of such examinations so arranged that comparison of vital facts recorded each year could be readily made and pathological changes quickly recognized. The weight, measurements (chest and abdomen), determination of blood pressure, the output of urine and its character, the examination of the chest, abdomen, and, at times, the blood would often indicate, if not incipient disease, at least a too liberal or improper diet; not enough exercise; too much physical or mental strain; insufficient recreation, unwise stimulation, etc. What would be our opinion of a business man who never took an inventory of his stock, who did not know at least once a year just what his assets were and also his indebtedness. Yet what physician takes thought until often too late, of his capital—his mind; his assets—an efficient body; his debts—possible incipient disease changes. Such an ex-

ample would be quickly followed by the intelligent layman and it would not be long before the best and most influential citizens would be regularly coming to our offices for their annual or semi-annual examination. (See chart below.)

It is not at all unusual for corporations to insure the life of a valuable manager for \$100,000 or more. A small sum expended for medical examinations each year might easily prolong such a life for years in a high state of efficiency.

Even the simple determination of blood pressure year by year would be most suggestive. Dr. Fisher of the Northwestern Mutual Life Insurance Co. has collated some illuminating statistics on this subject. The mortality of 2668 accepted risks of all ages, with a systolic blood pressure of 140 to 149 mm. Hg. average 142.43 mm, was 47 per cent. of the expected mortality. The mortality of 525 accepted risks of all ages with a systolic blood pressure of 150 mm. or over but averaging 152.58 mm. was 70.37 per cent. of the expected. The mortality of 365 rejected applicants with an average systolic blood pressure of 170.36, but with no other discoverable impairment was 144.51 per cent. of the expected.

The mortality of 356 rejected applicants with an average systolic blood pressure of 171.73 mm. and showing one or more other impairments was 161.99 per cent. of the expected mortality. The summary of Dr. Fisher's recent paper, shown on page 327, is so highly suggestive that I have taken the liberty of incorporating it after this address had been delivered.

OTHER EXAMS.					

All of us have had the sad experience of being consulted for some seemingly trivial condition by apparently strong, active, forceful men of affairs. The blood pressure would be 170 mm. or more, the urine of low specific gravity, with a faint trace of albumin and an occasional cast. The end was then inevitable. The pathetic thought must have occurred to each one of us—he might have been saved for years of useful life, if he had only consulted his physician earlier.

Every advance in the cure and prevention of disease has been due to the recognition of its cause and to the application of measures directed to eliminate or destroy such cause.

The same method, so successful in the acute contagious diseases, must be followed in the much more difficult problem of the chronic degenerative diseases.

Summary of Dr. Fisher's Paper.

The strenuous life even in play; the strain, worry and nervous depression due to the using up of reserve strength to keep up appearances, overeating and especially large meat consumption, the desire to work intensely with the hope of enjoying rest and ease later on, unfortunately a mirage which vanishes into thin air. Work under high pressure is the modern slogan and efficiency gone mad, the American god.

The correction of these causes means a reformation in the American character, but such a reformation must be made if the American nation is to reach that height of civilization and progress which seem its natural destiny.

In conclusion, consider for a moment what such a campaign would mean in the warfare against frauds, charlatans, and fakirs. The intelligent would quickly learn that there was no marvelous way to cure disease; that each one of us sooner or later must pay the penalty for our follies and indiscretions and that the only way to keep well is to prevent disease.

The accompanying schema for a physical examination which can be extended over a period of years is submitted for consideration and criticism.

Prophylaxis of Scarlet Fever.—Chantemesse has obtained excellent results with the prophylactic measures recommended by Milne. The throats of scarlet fever patients are painted with 10 per cent. carbolized oil at three-hour intervals day and night for the first 48 hours, and then twice a day for a further week. For children the strength of the oil is reduced. Daily frictions of the whole body with eucalyptus oil are used in addition. These measures have proved efficacious in preventing the spread of the disease.—*The Lancet*.

REMINISCENCES OF CHLORINE.

BY DOUGLAS H. STEWART, M.D., F.A.C.S.

NEW YORK.

CHLORINE and iodine are well known germicides that possess rare attractions for the pose of a pseudo-Columbus and his simulated pioneer work. The latter on careful examination will be found to progress along familiar paths. The history of one of these halogens, compared with the record of the other, reveals a curious seesaw semblance: for each of them in turn seems to be on the way down to the Valley of Discard, while the other is mounting to the heights of Reinstatement, from which it fell. Reasons for their erratic career might be derived from faddism, fetichism, wanderlust, or, as was said in a certain medical gathering—"If these gentlemen spoke the truth when they recommended a former technique, how are they speaking truth now? Or if they are speaking the truth now, were they not speaking it then?" Perhaps the old law is being followed. "And one by one in turn, some grand mistake casts off its bright skin, yearly, like the snake." In this instance, since there are but two substances, mistake and certainty must alternate. Chlorine, after proving its worth for fifty years, was supplanted by iodine for the absurd but sufficient reason that "chlorine was so very irritant." This statement permitted the impression that iodine was not irritating while it held tacit the facts that iodine was the world's best known counterirritant, and that its results, when used as a germicide, and strength for strength, were not so good as those obtained from chlorine. From 1900 to the present day, the author has tested the latter against pure and mixed bacterial strains, has brought it to the bar of the Petri dish, and has referred all final appeals to the microscope. Dr. Bull and Dr. Dawbarn urged the subject of hand-sterilization, as a very live matter indeed; and among some twenty-eight techniques, which were investigated, the one called by them "Weir's technique" soon proved itself to be preeminent. They stated that it was in use in the New York, Roosevelt, and other hospitals and both agreed that it was as follows (Date 1900 to 1905):

"Five minutes with green soap and vigorous nail-brush scrubbing; five minutes with frictional application of calx chlorinata; and finally, thorough washing off with carbonate of soda and running water." As an additional safeguard (not invariably used) the hands were immersed in 1/5000 bi-chloride solution.

Given a room with its windows closed, 90 per cent. of negatives were readily obtained and with care better results were possible. The yeasts only would sometimes slip through and could be propagated, but the aforesaid gentlemen took the ground that safety demanded absolute sterility, as its normal; inasmuch as no one could say whether, or when, pathogenic and non-pathogenic germs might not reverse their rôles, Labarraque's solution was neutralized and acidulated with dilute acetic acid, because that was selected as a solvent of calx chlorinata, by the U. S. P. of 1890. Washing the hands with a 3 to 6 per cent. strength of acetic acid would remove not only the calx but even its odor, which carbonate of soda would not do. The negative test cultures at once showed an increased percentage (5 to 8 in different trials). Omitting soda, the chemical antiseptics obtained by mingling the acid and the lime were considered to be nascent hypo-

chlorous acid plus nascent H_2O_2 , and the resulting solution bore no more chemical likeness to Labarraque's solution than acetic acid does to acetate of lime. Tartaric, boric, citric, lactic, and other acids were tried but the demand was for something that would stand boiling and be more portable and stable than a liquid. Consequently, two solids were finally adopted, viz., alum sulphate and calx chlorinata. A solution, which was boiled hard for five minutes, and then contained alum sulphate, 1 part, calx chlorinata, 2 parts, and water to 100 was made and was called Stewart's solution. Filtering or the use of the unshaken supernatant solution gave equally good results. Water that boiled away could be replaced or an extra allowance could be made for the loss by boiling. Boiling seemed to be essential for both solution and chemical combination. Full strength was used upon the surgeon's hands and half strength upon wounds or upon the site of operation. In one experiment 1 per cent. of the lime was added to the U.S.P. H_2O_2 solution and wrought such a distinct change from its usual non-bactericidal effects that as one man wrote me, "It almost lived up to the claims of its advertisements." A level teaspoonful of the alum plus a generous heaping teaspoonful of the lime, in two tumblers brimming full of water, only required to be boiled five minutes, and in a rough and ready way Stewart's solution could be approximated at any time or in an emergency (*Annals of Gynecology*, May, 1906, page 261). In short, while the original solution was Labarraque's acidulated with acetic acid (and other acids later) it soon became evident that the soda was not necessary and that acid alum had advantages. But the choice between alum and acetic acid always remained a matter of environment, adaptability, and portability. At present the alum solution is used (in one hospital at least) for an original or first cleansing of a septic wound and on this is placed a wet dressing of Wright's solution.

Repetition of the alum-chlorine is determined by the appearance of the wound at the second or any subsequent dressing. If all is well, then the citrate of soda solution is continued and the other omitted.

The whole technique of hand sterilization might be interesting. It was proven to be so very easy and efficient. Details of the many thousand tests and cultures were published long ago. The technique was: Five minutes, 3 of them with sapolio; add a handful of granulated sugar and rub carefully 2 minutes more. Plenty of water is taken for granted. Hand-test mixtures were inunctions of pus followed by rubbing on of asphalt dirt; no brush; no soap; rubbing continued until the grains of sugar were melted or dissolved. Then five minutes friction with the lime, which was washed off with dilute acetic acid (or vinegar.) For tender skins this latter was diluted one-half and then appeared to work quite as well. Often for the benefit of inquiring friends I have made a hundred successive cultures and scored one hundred negatives; in fact if used every day this method put the hands in such a condition that any good technique would be flattered, and I had to borrow the hands of others to see just what a technique was worth, because my own hands gave altogether too favorable results.

In applying chlorine to a wound, toilet paper should be used and gauze or other cotton wipes abandoned. Trial and estimation upon one's own skin will give a very good impression of the difference in friction, between the two, and explain why

one hurts a wounded patient so much more than the other. Iodine and many other things were tested, but for hand sterilization and vaginal work, chlorin-alum followed by Wright's solution (especially upon septic wounds) certainly promises well; unfortunately all but about a dozen or so of the patients were doing badly under iodine before the latter was applied, yet the change seemed advantageous. But, with plenty of material, perhaps some untreated wounds may come under observation; still the iodine cult, or furor, is so extensive that every druggist or first-aider, in a railroad or factory, immediately paints some of the tincture upon any and every wound. Lest some critic may quote my own words to my discomfort, it may be well to emphasize that the solution for which I admit responsibility is iodine, calomel, glycerin, and alcohol, and is no more like the tincture of iodine than Stewart's acidulated chlorine solution is like Labarraque's alkaline one.

At least twenty physicians have spoken to me about various writings that have lately appeared on the subject of an acidulated chlorine solution and it is at the suggestion of some members of the society before which the author's first paper was read (about twelve years ago) that this reminiscence is written. As for chlorine and its modified solutions for douches, enemata, lavage, etc., or for its mixtures with oils, or in ointments, these would each demand an article as long as this. But it may not be out of place to warn any experimenter that glycerin-chlorine is a dangerous mixture, the second and third degree burns from which had some value as mute witnesses against those chemists who maintained and explained that it would not explode. The human skin, friction, glycerin, and chlorinated lime are best kept from contact.

128 WEST EIGHTY-SIXTH STREET.

VACCINE THERAPY.

By G. A. EHRET, M.D.,

CLEVELAND, OHIO.

THEORETICALLY, bacterial vaccines should prove to be a valuable addition to therapeutics; practically, in my use of them they have so proven. However, in perusing the literature on the subject in our best medical journals, the reader is left much in doubt as to their value. My use of bacterins has covered a period of nearly two years and their practical utility has been demonstrated. My experience is confined principally to mixed stock vaccines, having used autogenous but a few times. As the value of any agent used in general medicine is finally determined by results achieved by the great body of general practitioners, it would seem rational to acquire data from their work.

No doubt a certain part of the observations of the general practitioner is inaccurate; but among the thousands of physicians now using bacterins there must be a large number who make fairly accurate observations and whose judgment is balanced and correct.

During a period of twenty-five years of active general practice one comes to a certain conviction of the value of any particular line of treatment. If on the institution of a new line of therapy, recoveries, as a rule, are more certain and prompt than with the treatment used for a period of years previously, it is difficult to escape the conclusion that the results are due to the new treatment.

If my results in the use of bacterins are similar to those of men of longer and wider experience in their use, it is corroborative evidence that the phenomena I have been witnessing are not exceptional but the definite result of a definite cause. The following list taken from case records during my first year's use of them contains cases where no doubt bacterins were given near the crisis of the disease. Experience convinces me, however, that bacterins hasten or even anticipate the crisis. In coryza and acute bronchitis, in which I consider them specific, my use of bacterins is routine. The following cases are submitted with the hope that other men in active practice will also give their experiences, whether favorable or otherwise, in the use of bacterial vaccines.

CASE I.—Colon Cystitis. G. A., 47 years, American. Cystitis of several weeks' standing. Pure colon culture found in urine by Dr. Sanford of Cleveland. April 15, 1912, a stock colon bacterin containing three hundred million organisms per c.c. was used, beginning with fifty million; dosage given every third day and gradually increased to 1 c.c. After six doses the urine was free of infection and symptoms disappeared.

CASE II.—Bronchopneumonia. Baby F., 8 months, female, Italian. February 15, 1914, saw patient at 10 A.M. Illness of 48 hours' duration. Temperature 105.2°. Rapid shallow respiration, rales diffused. Gave 10 minims of a stock bacterin containing, in millions of organisms per c.c., Friedlander bacillus, 300; *Micrococcus catarrhalis* 200; *Pneumococcus*, 80; *Streptococcus* 60; *Staphylococcus aureus*, 200; *Staphylococcus albus* 200. Repeated call that evening. Temperature 102°, respiration and pulse slower. Repeated doses of 10 minims. February 16, temperature normal, respiration normal. No further indications for treatment and recovery was uninterrupted.

CASE III.—Lobar Pneumonia. J. F. F., 36 years, male, Italian. Seen March 2, 1914, on third day of disease. Temperature 103.8°, pulse 156, respiration 52. Lower lobe of left lung consolidated. Patient delirious and picking at bed clothes. Removed to Canfield White Hospital. Gave 1 c.c. of stock bacterin used in Case II. at 5.30 P.M. Next morning at 8.45, temperature 101°. Repeated dose of 1 c.c. and mild laxative prescribed. At 5.30 P.M. temperature normal, pulse 86, respiration 22. Patient asked for food. Recovery uneventful and patient discharged from hospital able to walk to street car one week from date of entry.

CASE IV.—Chronic Gonorrheal Cystitis and Prostatitis. H. O. F., 26 years, American. Gonorrhea contracted when 18 years old. Repeated attacks. Treated by many physicians, he finally consulted an eminent genitourinary specialist, who diagnosed tuberculosis of the bladder on cystoscopic examination. March 12, 1914. Patient complained of pain in inguinal region and of being obliged to urinate often, up to six times during the night. Under prostatic massage secretion was expelled which showed gonococci, colon bacilli, and numerous other bacteria. Gave 10 minims of a stock bacterin containing, in millions of organisms per c.c., *Gonococcus*, 200; *Staphylococcus albus*, 800; *Streptococcus pyogenes*, 100; *Pneumococcus*, 100; *Colon bacillus*, 200. Dosage was gradually increased to 1 c.c. and given at five-day intervals. Continued treatment for six months with prostatic massage. Patient's body weight increased from 122 lb. to 148 lb. No other treatment used. Secretions showed absence of organisms. Seen recently and reports he has remained absolutely well.

CASE V.—Gonorrheal Arthritis. O. G., 36 years, American, male. March 14, 1915. Gonorrhea followed by arthritis of right shoulder joint, wrists, and left ankle. Used Bier's hyperemia with some benefit. Used stock bacterin of formula used in Case IV. Initial dose 10 minims. Terrific local and general reaction. Next day gave 5 minims. Pain less severe, less reaction. Gave 5 minims daily for ten days. Recovery complete.

CASE VI.—Lobar Pneumonia. Mary B., 28 years, Italian. March 17, 1914. Patient seen at end of tenth day of disease. Temperature 104.5°, pulse 120, respiration 56. Lower lobes of both lungs consolidated. Rusty sputum and blood. Patient had been on orthodox treatment. Removed to Canfield White Hospital. Gave 1 c.c. of stock bacterin used in Case II. at 5.30 P.M. At

7.30 P.M. crisis occurred temperature dropped to normal and remained so. Lungs did not clean up, however, and I gave ½ c.c. same bacterin at intervals of two days. Patient discharged well at end of two weeks in hospital.

CASE VII.—Lobar Pneumonia. A. V., 31 years, male, Italian. March 24, 1914, called to see patient, found classical symptoms of lobar pneumonia. Temperature 103.5°, respiration 32, pulse slow and bounding. Rusty sputum. Lower lobe of right lung consolidated. Removed to Canfield White Hospital. Gave 1 c.c. stock bacterin used in Case II. March 25, temperature 99°, pulse 82, respiration 26. Repeated dose of 1 c.c. at 9.30 A.M. At 6 P.M. temperature normal. No other indications for treatment and patient discharged on fifth day after entry.

CASE VIII.—Chronic Articular Rheumatism. Mrs. C., 35 years, American. History of acute rheumatism three years previously. April 16, 1914. Present condition: knee-joints and right ankle enlarged and painful. Suggested bacterins as a possible help. Began with 5 minims of stock bacterin containing, in millions of organisms per c.c., *Streptococcus pyogenes*, 60; *Pneumococcus*, 80; *Staphylococcus albus*, 200; *Staphylococcus aureus* 200. Five-minim doses at five-day intervals were given. No improvement until the tenth injection, when the pain ceased. The patient then disappeared from the office for a year. I saw her at the end of this time and she said she was perfectly well and had taken no other treatment since.

CASE IX.—Neuritis. Mrs. M., 46 years, American. Patient seen July 9, 1914. Neuritis in both arms. Nerves tender on pressure. Four years previously patient took electrical treatment for same, then went to a Sanatorium and remained eight weeks, returning home much improved. Remained comparatively well for a year. Returned to me in 1913 with pain much more severe than ever. I tried electricity, etc., with no benefit. Patient very constipated and usual remedies for same gave little relief. An x-ray of the intestinal tract showed dilatation of the stomach. In July, 1914, I suggested bacterins as last resort. July 16, 1914, gave 10 minims of stock bacterin containing, in millions of organisms per c.c., *Streptococcus pyogenes*, 100; *Pneumococcus*, 100; *Staphylococcus aureus*, *albus*, and *citreus*, each 200; *Colon bacillus*, 200. Doses were given at intervals of five days and gradually increased to 1 c.c. Twenty-four injections were given with complete subsidence of symptoms. Abdomen massaged and strapped and constipation entirely relieved. The patient has been under observation and has remained well up to the present time.

CASE X.—Bronchial Asthma. Mrs. S., 42 years, American. History of bronchial asthma for six years. Treatment along usual lines. Patient was willing to try bacterins if she could hope to get relief. May 12, 1914, gave 10 minims of stock bacterin used in Case IX. Gave six doses, the last one of 7 c.c., at four-day intervals, and symptoms entirely disappeared. Have seen her from time to time since and she has had no return of asthma.

CASE XI.—Bronchial Asthma. James B., 46 years, American, merchant tailor. Usual symptoms of bronchial asthma, dyspnea severe upon climbing stairs. Patient had tried many remedies and treatments. Sept. 1, 1914, gave bacterin used in Case II beginning with 10 minims. Severe local reaction followed with chill and the patient was obliged to go to bed. Sept. 4 gave 5 minims. Reported next day he felt much better. Sept. 7 gave 10 minims. Patient so much better he considered it unnecessary to take further treatment. He has no dyspnea and climbs stairs to his work shop with no difficulty. He has since referred a number of patients to me.

CASE XII.—Otitis Media. Baby P., 3 years, American. Usual history until rupture of tympanic membrane when I was called. Sept. 14, 1914, I gave a stock bacterin containing, in millions of organisms per c.c., *Streptococcus pyogenes*, 60; *pneumococcus*, 80; *Staphylococcus albus* and *aureus*, each 200. Initial dose 3 minims and repeated every third day. No other treatment used except to wipe pus from external ear. Symptoms rapidly improved, and ear entirely dry at end of second week.

CASE XIII.—Central Pneumonia (?) Baby Frank C., 5 years, American. Baby sick two weeks when first seen, Nov. 8, 1914. Temperature had averaged for the two weeks, morning 102°, evening 105°. Cough and pneumonic symptoms absent. Slight dilatation of alæ

nasi. Typhoid fever suspected, but Widal was negative. I was unable to define the lesion and requested a consultation with Dr. H. J. Lee of Cleveland who inclined to a diagnosis of central pneumonia. Temperature at consultation 105.5°, respiration 56, pulse 140. Patient restless, insomnia. Expectant treatment advised and I suggested using a mixed catarrhal stock bacterin. Consultant demurred as he thought bacterin useless, but consented to try it. Gave immediately 0.5 c.c. of bacterin used in Case II. Temperature dropped to normal in two hours and child fell asleep. Recovery uninterrupted.

CASE XIV.—Otitis Media. Mary S., 22 years, American. History of otitis media since age of two years. Right ear affected and discharging pus. Dec. 15, 1914, gave 10 minims of a stock bacterin containing, in millions of organisms per c.c., *Staphylococcus aureus* and *albus*, each 600. Dose repeated at five-day intervals and increased to 1 c.c. No improvement. Bacterial diagnosis showed culture of *Streptococcus mucosus*. An autogenous bacterin was prepared and an initial dose of 30 million organisms was given and increased every five days. Hearing was improved and the discharge had almost ceased when the patient discontinued treatment.

CASE XV.—Bronchial Asthma. Mrs. V., 38 years, American. History of asthma for many years. Gave stock bacterin used in Case II, beginning with 5 minims increased to 1 c.c. and given at five-day intervals. Treatment continued six weeks. No benefit whatever.

CASE XVI.—Bronchial Asthma. Max P., 26 years, American. Asthma several years standing. Patient was laboring for air when he entered my office. Attacks aggravated during wet weather. Diagnosis of bronchial asthma confirmed on physical examination. Dec. 27, 1914, gave 10 minims of stock bacterin used in Case II. Reaction very severe. Repeated 10 minims in one week. Patient stated he would rather have the asthma than the sore arm. Next dose of five minims, given five days from last injection, gave mild reaction and patient reported feeling better. From this on, the dosage was given at five-day intervals for a period of six weeks, the maximum dose being 1 c.c. All asthmatic symptoms cleared up and he has had no return of the trouble.

A FATAL CASE OF CEDAR OIL POISONING.

By WM. D. McNALLY, A.B.,

CHIEF, COOK COUNTY CORONER'S LABORATORY.

THE literature since 1845 contains a record of only 19 cases of cedar oil poisoning; 13 were abortion cases, four of them ending fatally. The case which I have to report is that of a young negro woman, 22 years old. The clinical data in the case have been kindly furnished by Dr. S. N. Balderston. Briefly the symptoms were—convulsion, bloody froth at the mouth, irregular breathing, weak pulse, and a cold, clammy skin. The stomach was washed out; the washings had the odor of oil of cedar. Within one hour of taking the oil, the patient died.

The stomach containing 464 grams of contents and weighing 120 grams was submitted to me for examination. Upon opening the stomach a pronounced odor of oil of cedar was noticed. The stomach was hashed and 100 grams subjected to a steam distillation. The distillate yielded but a trace of the oil. The stomach contents were thoroughly mixed and 100 grams acidulated with a few drops of 10 per cent. sulphuric acid and filtered through cheese cloth. The filtrate was extracted with ethyl ether and allowed to evaporate at room temperature. A clear oil was obtained having the odor of oil of cedar. It had an index of refraction of 1.470 at 17° C. From 584 grams of the stomach and contents 5.13 grams of oil was recovered.

A three ounce bottle, bearing a label, "Oil of Cedar Leaf," was found in the room of the deceased.

One ounce had been removed. The oil had been purchased at a neighboring drug store a few hours before the woman became ill. The contents of the bottle had a specific gravity of .9383 at 19° C, and a refractive index of 1.471 at 17° C.

Twenty-five c.c. of the oil was distilled with the following result:

Temp. C.	C.C. Fraction	R. Index at 17 C.
Below 78	0.5	1.365
180	1.5	
196	5.5	1.462
200	11.0	1.466
220	4.0	
230	1.0	1.470
Loss and tarry residue	1.5	
Total	25.0 c.c.	

The largest portion of this oil distilled at 200° C. The major portion of pure oil of cedar leaf, distills over below 173° C.¹ The specific gravity of pure cedar leaf oil is from .886 to .920. Pure cedar wood oil has a specific gravity of .940 to .960 and a high refractive index of about 1.505 at 17° C. The above oil examined corresponds more with cedar wood oil than cedar leaf oil.

A number of tests were made on animals with pure oil of cedar leaf with the following results:

Weight	Dose	Result	Remarks
Rabbit No. 1 647 grams	4 c.c.	Convulsions	Death in ten minutes.
Rabbit No. 2 391 grams	4 c.c.	Convulsions	Death in two minutes.
Rabbit No. 3 2000 grams	4 c.c.	Shakiness	
Rabbit No. 4 2000 gram pregnant	4 c.c.	Shakiness	Aborted during the night; did not die.
Rabbit No. 5 2599 grams	1 c.c.	Shakiness	Did not die.
Rabbit No. 6 4164 grams pregnant	1 c.c.	Convulsions	Dead in two minutes without abortion.
Dog No. 7 5.5 kilos (pregnant)	4 c.c.	Convulsions	Dead in fifteen minutes without abortion.
Dog No. 8 6.0 kilos, 1st day	2 c.c.	No effect	Twelve hours.
Dog No. 8 6.0 kilos, 2d day	3 c.c.	No effect	Twelve hours.
Dog No. 8 6.0 kilos, 3d day	4 c.c.	No effect	Twelve hours.
Dog No. 8 6.0 kilos, 4th day	10 c.c.	Vomited	After six hours began to eat, active as ever.
Dog No. 8 6.0 kilos, 5th day	17 c.c.	Vomited	Had tetanic convulsions, attributed to the great pain, stertorous breathing, pupils dilated, would bite at wire cage. Unconscious part of the time. Had violent tetanic convulsions every ten minutes for one hour. Urine voided had odor of oil of cedar. Dog lived ten hours, appeared very weak and in pain, was then anesthetized with ether until heart stopped.
Dog No. 9 8 kilos	25 c.c.	Convulsions	Vomited, died in 50 minutes.

A small dose seemed to have a greater effect on pregnant animals than on non-pregnant animals. A post mortem examination on dog No. 7 showed an intense hyperemia of all organs. The fetal membrane showed extreme venous engorgement.

I am indebted to Dr. H. G. W. Reinhardt, Coroner's Physician, for a brief synopsis of the necropsy findings twelve hours after death.

There was an edema of both lungs. The heart was normal in size, the myocardium, endocardium, and the valves appeared normal. There was an increase of the pericardial fluid. The peritoneum was smooth and glistening; the vessels of the omentum, mesentery, and pelvis were deeply injected. The stomach was acutely dilated. The subserous vessels of the lesser and greater curvature were intensely engorged. Upon opening the stomach a strong odor of oil of cedar was noticed. The serosa of the small intestine appeared normal; there was a distinct hyperemia of the mucosa of the large in-

testine. The liver was slightly enlarged, with intense congestion. The pancreas appeared normal. The spleen was of normal size. The kidneys were slightly enlarged, of a dark red color, the capsule stripped easily leaving a smooth surface. On section both cortex and medulla appeared hyperemic. The urinary bladder was empty. The mucosa was hyperemic. The uterus was enlarged and contained a fetus of about six weeks gestation, the membranes were intact. The ovaries and tubes were markedly congested. The right ovary was enlarged and upon section a corpus luteum of about .75 cm. in diameter was found.

A few cases² of accidental poisoning have been reported. One of these was due to a pharmacist's error.³ In another case the oil was used in the treatment of gonorrhea.⁴ Wait⁵ reported four cases, in one of which a young man who had seduced a girl was convicted of her murder. In the second case a young woman, age 26, who took a "large spoonful" recovered with treatment. In a third case, a girl 17 years of age, took one ounce and recovered with treatment. In the fourth case, a woman, age 32 years, died within one hour from taking an unknown amount. Branden⁶ reports a case in which a woman recovered from taking one drachm. In Thompson and Archibald's⁷ case, in which an unknown amount was taken, the woman died. In Brown's⁸ case, the woman took one-half ounce of oil without aborting. The symptoms consisted of dizziness, frothing at the mouth, violent convulsions, unconsciousness, dyspnea, cold perspiration, and suppression of the urine for 36 hours. Other cases⁹ have been reported, but in no instance did the woman abort.

Medicolegal Notes.

Malpractice—Pleading Specific Act of Negligence.—In an action for alleged malpractice in the treatment of the plaintiff's husband during an attack of typhoid fever which resulted in his death, the plaintiff alleged a specific act of negligence, namely, the prescribing for the patient a diet of poached eggs and toasted bread, whereby his bowels were perforated and torn, it was held that, the plaintiff having charged the defendant with a specific act of negligence, could not, under that charge, introduce evidence of other acts and attempt to show negligence therein, although she was not obligated to plead her evidence or set out in detail specific acts, and judgment for the plaintiff was reversed.—*Ennis v. Banks*, Washington Supreme Court, 152 Pac. 1037.

Contract for Physician's Services Payable by Installments—Effect of Patient's Death.—A patient agreed in writing to pay his physician "five thousand dollars for his treatment of locomotor ataxia, divided into payments as follows: Five hundred dollars every three months till paid." The patient took the treatment for twenty months and then died. In an action against his

estate it was held that the physician was entitled to recover the whole of the unpaid portion of the \$5,000. Such a contract is not against public policy. It is an entire contract; and the court will not apply to it the principle that in contracts for personal services it is an implied condition that the death of either party dissolves the contract. The court said that a very important thing to be considered in the construction of the contract was that it did not name any period of time during which the treatment was to continue.—*Smith's Estate*, 59 Pa. Superior Ct. 4.

Infection from Unsterilized Instruments—Hypothetical Questions.—In an action against a dentist to recover damages for injuries to the plaintiff's jaw, the evidence for the plaintiff tended to show that the defendant after having operated on a patient for an abscess of the jaw, immediately afterwards, without having washed his hands, or cleansed or sterilized his instruments, cut the plaintiff's gum after having drilled a tooth, which was sound, at a point where there was no ulceration, and that a few days afterwards the gum ulcerated, resulting in necrosis of the jaw and the ultimate removal of a portion of the jawbone. It was held that the case was for the jury, and a verdict and judgment were sustained. An expert called by the plaintiff was asked a hypothetical question as follows: Suppose a person after having lanced an abscess in one patient without washing his hands, undertakes to lance the gums of another patient, but before doing so handles the cutting part of the blade of the knife with his hands or fingers, and that second patient develops an abscess at the point where lanced a few days later, to what would you attribute that abscess?" "A. Well, to infection." It was held that the question was a proper one.—*Norwood v. Goeddel*, 58 Pa. Superior Ct. 500.

X-Ray Photographs—Hypothetical Questions.—In an action for personal injuries, it was held error to permit doctors, over objection, to testify what an x-ray photograph of the plaintiff's person showed without producing the photograph, for the reason that the photograph was the best evidence.

A hypothetical question, which began: "Assuming that a man whose present condition is as you disclose the condition of plaintiff to be," was held improper, for the reason that the question should have in it all the facts on which the answer is based.—*Hammond v. Bloomington Canning Co.*, 190 Ill. App. 511.

Injuries from Hot-Water Bottle.—In an action against a sanatorium and its superintendent it appeared that the plaintiff had employed the superintendent to perform an operation for hernia. After the operation was performed the doctor carried the plaintiff to the room assigned to him and placed him in bed while still under the influence of an anesthetic. A rubber bottle, filled with very hot water, had been placed in the bed, and the unconscious man was laid upon it, and was burned on his back severely. The witnesses described the wound as being 15 to 18 inches in diameter. He also received a smaller burn on his side; the attendants, believing that his struggles on becoming conscious were due to delirium, having held him down on the bed for a time and then turned him on his side. He was under treatment from the burns for a number of months and suffered excruciating pain. The jury found the doctor, but not the sanatorium, guilty, and rendered a verdict for \$5,000, which the trial court reduced to \$2,500. On appeal, the court said that it did not mean to condemn the doctor, nor even to say that he was in fact negligent; but, taking the situation as it found it, and as the jury observed it, there was evidence to justify them in finding that the doctor had not exercised proper care; and, having so found, the court had no right to dispute the verdict. It also held that the damages awarded were not excessive.—*Grosshart v. Shaffer*, Oklahoma Supreme Court, 152 Pac. 441.

Exemption of Charitable Hospital from Taxation.—Under section 170 of the Kentucky Constitution, exempting institutions of purely public charity from taxation, a hospital incorporated by trustees as a charitable corporation having no capital stock and holding property for the maintenance of a hospital for the treatment of sick and disabled persons and for medical and surgical treatment and the maintenance of poor persons not able to provide it for themselves, maintained without pecuniary profit, and having funds invested the income of which was used solely in meeting the necessary expenses, was an "institution of purely public charity," whose invested fund was exempt from taxation.—*Mason County v. Hayswood Hospital*, Kentucky Court of Appeals, 179 S. W. 1050.

A THEORY OF DEVELOPMENT THROUGH FUNCTION.

THE fact is well-known and accepted that the complex and highly differentiated organ or system has been developed from a very simple form. Comparative morphology has firmly established that. But what are the causes of such development, the principles of life and the properties of living matter which bring it about? There are those who see an inherent development in the form which produces a complexity of functioning in relation to the environment. Certain investigations, however, suggest the primary importance of function in the evolutionary process.

S. T. Bok of Amsterdam discusses in *Psychiatrische en Neurologische Bladen*, 1915, Nos. 4 and 5, a theory of functional development of the nervous system, his hypothesis being formulated with simplicity and clearness and based upon detailed observations made upon a chick embryo with a consideration of the new facts thus ascertained. He has discovered through new and fine staining methods a system of tracts, a "ground plan" of the nervous system, at once schematic and comprehensible. The striking thing about it is its rectangular appearance, which shows the new neuron in a reflex arc always perpendicular to the previous arc. These observations are important in determining when and where new tracts begin and what their course will be.

The first law is discovered through the position and direction observed in the first outgrowth of neurites. The law is formulated thus: New tracts always originate in neuroblasts situated in the environment of already existing tracts. Since, however, as has been well-established, the neurite grows out sooner than the dendrite, the young neuron has no contact with the activating tract at first. This is stated as the second law. There must then be some sort of bridge through which the action takes place. The third law must cover this. In order to understand this law Bok considers hypothetically an animal that in its adult form stands at the same level as that of the chick embryo under observation. Here stimulations would pass at certain moments and these irradiated stimuli, passing from axones that lie naked in the protoplasm, must emanate into the surrounding protoplasm. This emanation would occur at all unmyelinated tracts when stimulated, but chiefly where there is an accumula-

tion of stimuli. From this the third law is manifest. The new fibers develop in the direction of these stimuli which emanate from the activating tract. Striking examples of the operation of this law may be found in the preponderance of longitudinal and cross fibers in the spinal cord and bulb, also in the structure of the tectum opticum, where the secondary fibers are perpendicular to the opticus fibers, and the tertiary fibers take a third perpendicular course.

It is the protoplasm which adapts itself to the conduction of stimuli, especially through its so-called mnemonic power, that which allows a function once performed to be performed more easily a second time. This adaptation results in the formation of neurofibrils. New tracts, therefore, arise when constantly repeated stimulus currents emanate from already existing tracts; the cells which are first pervaded by these stimuli then send out their axis fibers in the direction of these currents. This the author formulates as his hypothesis of the origin of fibrillation from stimulation. The course also of the tract thus formed is determined through function. Following the law of neurobiotaxis the fibers seek simultaneously stimulated regions. Thus the afferent skin fibers or the vestibular fibers, which conduct widely extended stimulation, bend toward each other in the sensory bundles along the lateral root line. On the other hand, a merely local stimulation results in the fibers running through on the same levels.

There are two explanations for this law of neurobiotaxis, which seems to limit to a large extent the course of the neurites. One is the scientific theory that stimuli, which represent a form of energy as yet unknown biologically, will attract each other. The other lies in this theory of fibrillation arising from stimulation, because simultaneously stimulated points are doubly pervaded by stimuli and the protoplasm is thereby adapted to repeated function.

The complexity and diversity of the nervous system might, therefore, be wholly accounted for by this theory of the origin of fibrillation from stimulation. Function appears as the initial factor and the cause of the anatomical substratum. The author, in a fuller discussion of this same hypothesis (*Folia Neurobiologica*, 1915, IX, 5), finds in this conclusion a value beyond the merely anatomical, which gives it a higher significance in the neurological and psychical problems of to-day. He expresses this in the pregnant words of Schiller: "It is the spirit, which to itself the body moulds."

OCCUPATIONAL DISEASES AND INDUSTRIAL HYGIENE.

OCCUPATIONAL diseases are, of course, very prevalent. The pity and in many instances the shame of it is that such diseases may be prevented. Some occupations are notoriously unhygienic, and it is difficult to provide precautions which will rid them of their disease-conveying tendencies, but, on the other hand, much can be done, which is left undone, to better and render more hygienic the condition of toilers, even in the most menacing occupations. Often, perhaps most frequently, bad con-

ditions in workshops and factories are allowed to exist and continue for economical reasons. Employers are only too often more intent on making money than careful of the health of their employees and have to be compelled by law to safeguard the lives and bodily welfare of those who work for them. It also occasionally happens that laws when made are not enforced. In the recent report of the Surgeon General of the Public Health Service the question of occupational diseases and industrial hygiene is discussed at some length. During the year investigations of occupational diseases and the hygiene of workers have been carried on under the direction of Surgeon I. W. Schereschewsky. A comprehensive investigation begun in the fiscal year 1914 was concluded in 1915 and the results recorded in the report. The persons examined belonged to the cloak and suit, and dress and waist industries in New York City, which employ a total of 86,000 individuals. The incidence of defects and diseases was noted in the case of 3,086 workers, and there were recorded 13,457 defects and diseases of all kinds, of which 9,541 were in males and 3,916 in females. The examination showed no vocational diseases peculiar to the garment worker. Nevertheless, it was evident that the effect of sedentary occupations, such as women's garment industries, was to intensify the bad effects upon health and efficiency of certain defects and diseases or to produce them in predisposed individuals. Tuberculosis is the most prevalent disease among garment workers, 3.11 per cent. of the males examined and 0.9 per cent. of the females being found to be tuberculous. Apart from tuberculosis, the most common defects and diseases among garment workers, in order of frequency for both sexes were defective vision, 69 per cent.; faulty posture, 50 per cent.; chronic nose and throat affections, 26.2 per cent.; defective teeth, 26 per cent.; pyorrhea, 26.2 per cent.; dysmenorrhea, 20.2 per cent.; hypertrophied tonsils, 15.3 per cent.; defective hearing, 10 per cent.; nervous affections, 7.75 per cent. The investigation resulted in the making of recommendations to the joint board of sanitary control for the improvement of conditions under the board's jurisdiction. Stress was laid upon education as a means of improving the knowledge of personal hygiene of the worker, the lack of which plays an important part in the causation of the defects and diseases noted in the examinations.

With respect to economic conditions and their relation to the public health, Surgeon Warren submitted a report in which he showed how intimately the problem of disease prevention is related to industrial and economic problems and the necessity for cooperation between public health workers and those endeavoring to solve our economic problems. Hygienic standards were defined and outlined according to responsibility. The most important of these were discussed in order to show the relation of insanitary conditions in places of employment, long hours of labor and fatigue, poor living conditions, cost of living, wages and income, and woman and child labor, to the health of the individual worker and the community. The relation was especially shown by the sick and death rates accord-

ing to occupation and their effect upon the infant mortality. The relation of sickness to labor unrest was also pointed out.

As we have said, the question of the health of workers is of the utmost concern, not only to the workers themselves but to the community at large. It is obviously false economy and bad policy to avoid taking precautions to guard the health of workers because it costs something. Viewed even from the purely selfish standpoint, it is not economical in the long run. The good health of the people is the greatest national asset, for if disease is engendered and its progress encouraged by the neglect of the laws of health, like a boomerang it will strike those responsible for the conditions and in time will undermine the health of most of the inhabitants. If disease flourishes man will decay and the nation of which he is a part will disintegrate and come to naught. Therefore laws should be made and strictly carried into effect which are best calculated to conserve the health of the workers. The Public Health Service is doing good work in this direction, and its efforts should be forwarded by the authorities that be.

WAR NEURASTHENIA AND HEART DISEASE.

OUR textbooks on neurasthenia state that as a rule this affection is endogenous and appears on a neuro-pathic substratum; while exogenous neurasthenia, although well marked examples are now and then seen, is relatively rare. The occurrence of earthquakes and similar cataclysmic events has of late years been recognized as equal to the production of neurasthenia in the untainted. But common as this affection has been in its endogenous expression, it is probable that the exogenous form, as determined in the healthy by war hardships, is at the present day far more in evidence than its fellow affection.

Thus Stadelmann, stated to the Berlin medical Society last November (*Berliner klinische Wochenschrift*, November 29) that fully one-half of the invalided soldiers who came before him suffered from neurasthenia—there was literally a great army of these sufferers. They had symptoms without end, but from 50 to 70 per cent. complained of their hearts. Objectively but little could be found to explain the symptoms—perhaps in not more than 5 per cent. of these subjects were there objective finds. Contrary to what is often seen in peace practice, information that no heart disease was present was not well received. These patients are so demoralized that they do not even wish for recovery, which would surely involve a return to the front. All they desire is to return home and take up their regular vocations.

Hence there is a conflict between the surgeon and the patient, for the former's duty is to get the latter back in the ranks as soon as possible. The first step is to refuse a return to the home, which must be replaced by a convalescent sanatorium. At present most or all these are in the West. In any case, these subjects must for obvious reasons be kept away from the great cities. The author further suggests that the men should be kept in ignorance of the diagnosis of their ailments.

THE FUTURE STATUS OF ALCOHOL DRINKING IN GERMANY.

GERMAN efficiency owes nothing to sentimentalism or fanaticism so that the problem of alcoholism is dealt with in a manner radically unlike that affected in the United States. It is admitted that the Empire on a peace footing comprises from 300,000 to 400,000 "alcohol-sick" individuals. These men are heavy drinkers but not necessarily drunkards. In reading miscellaneous case histories, irrespective of the nature of the disease, the patient is often mentioned as an "alkoholiker" or "alkoholist" and his daily consumption of alcohol is given, along with the lesions due to or aggravated by his addiction over and above his special ailments. Such men as a rule attend to their occupations and are husbands and fathers of families. The consumption of the drug is interdicted or greatly curtailed and the patient's health is duly benefited. The first step in solving the problem is to reach this class of people, and this is most wisely done by proper instruction in youth. Many Germans are said, for example, to believe that the use of alcohol protects them from infectious diseases. It is only by teaching the young the falsity of this belief that it can be finally dispelled.

Again the success of restrictive measures in warfare has taught that a certain amount and kind of restriction in times of peace will work no hardship. At present it is too soon to formulate these restrictions but they will clearly come under two heads. First, uniform laws, statutes of central origin, and, second, local police regulations as determined by local exigencies. Enlightenment is of course not to be limited to school children, but will be extended to parents and adults in general. It must take two forms, one dealing with alcohol-temptation—which must differ somewhat with local customs—and alcohol-danger. These features were brought out in detail during a recent Conference for Public Welfare held in Berlin (*Deutsche medizinische Wochenschrift*, December 2). In contrasting German reform methods with our own it is only just to remark that in Germany there are no such subsidiary problems as saloon politics and negro alcoholism and drug addiction.

ACUTE RENAL CONGESTION IN THE TROOPS IN FRANCE.

LIFE in the trenches, even when the enemy is not engaged in bombarding him, is not all "beer and skittles" for Tommy Atkins. A number of painful conditions arise as a result of exposure to wet cold, of insufficient sleep and nervous tension. These symptom complexes are being named according to the part of the body they attack, as "trench back," "trench foot," etc. A development, the connection of which with conditions in the trenches is not obvious, is a transient nephritis which seems to attack soldiers who have been on active duty for long periods. In the *British Medical Journal* for July 17, 1915, an account of a number of such cases appeared. The writer, who was anonymous, came to the conclusion that the soldiers affected must have been exposed to some toxin of unknown character which had a selective action on the renal

epithelium. In the same journal for September 25, Dr. Raw reports five cases of this malady. All these patients had albumin and casts, three of them had high specific gravity; in the other two this is not mentioned. All the men recovered. A common feature of all the cases of both these writers was that there had been no previous kidney trouble. Many theories have, of course, been advanced to account for this condition which appears to be associated in some way with life in the trenches. In the above-mentioned journal for October 9 last Dr. Abercrombie describes and discusses this form of nephritis at great length. He is inclined to believe that it is due to some specific organism which has not as yet been isolated. Developments since his article would seem to indicate that it is either a streptococcic or a colon infection. We occasionally see in civil practice a case of acute nephritis developing in an individual who has been put to some unaccustomed strain and these not improbably belong in the same category.

THE HUMAN AURA.

VARIOUS quasi-scientific publications in recent years upon human emanations, x-rays, and allied subjects have not been accepted seriously by the leaders of the medical profession, probably because of their imperfections rather than of their intrinsic improbability. Students along these lines had not made out a case, and in addition the subjects smacked too much of spiritism. So far as we know the great scientists who have investigated the phenomena of spiritism and have in some cases become converts to the latter belief, have not expressed themselves *ex cathedra* on the validity of the finds in question. Recently Professor Benedikt of Vienna has made studies along these lines. At a meeting of the Royal Imperial Society of Physicians of Vienna (*Berliner klinische Wochenschrift*, December 13) he stated without comment that when a normal human being is placed in a dark room the face appears blue, the left half of the body blue, and the right half red or orange. A woman who claimed to be able to locate objects with a divining rod seemed broader in the chamber than was actually the case. In particular the thumbs seemed much larger. Another of these women gave off an emanation for part of the time only. Both the women were said to be able to locate water, coal, oil, and metals, the second one only when these were beneath the ground, while the first was also able to find them when concealed in a room. The second woman had a tender area over the spine, and when the rod was placed upon this area violent pains were experienced.

News of the Week.

City Death Rate Drops.—The death rate in New York for the week ending February 5 showed a marked decrease as compared with the previous week and was but slightly higher than the rate for the corresponding week of last year. The decrease in the deaths from influenza, bronchitis, and pneumonia were responsible for the lowering of the rate. During the week of January 29, 1916, there were 1,812 deaths from all causes, giving a rate per 1,000 of 16.46; during the week of February 5, 1916, 1,547 deaths, a rate of 14.5, and during the week of February 6, 1915, 1,464 deaths, a rate of 14.13. Influenza caused 46 deaths, pneumonia 292,

and heart disease 340, during the week of February 5 of this year, as compared with 81 deaths, 339 deaths, and 424 deaths respectively, during the week of January 29.

Insane Hospital Needed.—The New York State Hospital Commission is urging that the proceeds of the suggested sale of the Mohansic State Hospital site be used for the purchase of another site and the erection of a hospital near New York City. The commission believes that this action is imperative because of the overcrowded condition of the State hospitals for the insane, particularly those near the city. The capacity of all the fourteen State hospitals is 27,840 patients, but at the present time they are housing 6,484 patients over the number of those who can be properly accommodated, and each year the overcrowding becomes worse.

The Mary Putnam Jacobi Fellowship.—The Woman's Medical Association of New York City offers the Mary Putnam Jacobi Fellowship of \$800, available for postgraduate study. It is open to any woman physician for work in any of the medical sciences. The fellowship will not be awarded by competitive examination, but upon proof of ability and promise of success in the chosen line of work. Applications for the year 1916-1917 must be in the hands of the committee on award by April 1, 1916, and must be accompanied by (1) Testimonials as to thoroughly good health; (2) Letters as to ability and character; (3) A detailed account of educational qualifications; (4) A statement of the work in which the applicant proposes to engage while holding the fellowship; (5) Examples, if any, of her work, in the form of articles or accounts of investigations which she has carried out. Two reports will be expected from the holder of the fellowship, one to be presented about the middle of the work and a detailed report for publication upon its completion. All applications for this fellowship shall be forwarded to the committee: Annie S. Daniel, M.D., chairman, 26 Gramercy Park, New York City; Martha Wollstein, M.D., Helen Baldwin, M.D., Angenette Parry, M.D., Eleanor Tomes, M.D., Rose Cohen, M.D., Josephine Hemenway Kenyon, M.D., Emily Dunning Barringer, M.D.

Personals.—Prof. ELIE METCHNIKOFF, who has been critically ill, according to recent reports from Paris, is now improving and is considered to be out of danger.

Dr. C. G. L. WOLF, formerly assistant professor of chemistry in the Cornell University Medical College, New York, and now a captain in the Royal Army Medical Corps and stationed at Boulogne, has recently been named in the despatches of General French as the recipient of the "Distinguished Service Order."

Dr. PARKER SYMS has been appointed visiting surgeon to the City Hospital, New York.

Dr. GUSTAV SCHOLER has been nominated by Governor Whitman as a manager of the Manhattan State Hospital.

Dr. S. GINSBERG of the Bronx, New York, announces his removal to 1451 Prospect Avenue.

Dr. GORHAM BACON, professor of otology at the College of Physicians and Surgeons, New York, has tendered his resignation, which has been accepted by the trustees of the university, to take effect at the end of the present academic year.

Prof. Ivan P. Pavlov, chief of the department of physiology of the Institute of Experimental Medicine and director of the physiological laboratory of the academy, Petrograd, and the recipient of the

Nobel prize for medicine in 1904, died recently at the age of 67 years.

Ohio State Medical College.—At the meeting of the trustees of the Ohio State University, Columbus, on February 8, Dr. Eugene F. McCampbell, executive secretary of the Ohio State Board of Health, was elected dean of the College of Medicine of the University, succeeding Dr. W. J. Means, resigned. Dr. McCampbell will shortly resign as secretary of the health board and will devote himself to the reorganization of the medical school.

Smallpox in New York.—A case of smallpox was reported on February 9 in Bayside, Queens Borough, New York. The patient, a negro, was removed to the Kingston Avenue Hospital for Contagious Diseases, Brooklyn.

Hospital Study.—At the suggestion of the public health committee of the New York Academy of Medicine, the American College of Surgeons has undertaken a systematic study of hospitals, their standards, their efficiency, and their relation to medical education. The Carnegie Foundation of New York will cooperate with the college in its undertaking and give such financial assistance as may be necessary.

Blindness from Wood Alcohol.—The plaintiff in a trial in Baltimore recently was awarded \$7,500 for the loss of his sight as the result of drinking whiskey which had been diluted with wood alcohol. The jobber and the saloonkeeper were held jointly responsible for the damages, the testimony showing that the drink had been diluted as claimed and that the victim lost his sight a day or two after he had drunk a part of the two pints purchased.

Liners for Hospital Ships.—The 48,000-ton liner *Britannic*, the largest British ship afloat, is now being used as a hospital ship, having been converted by the British Admiralty immediately after her launching. The *Mauretania* and the *Aquitania* also are being similarly used.

Requests to Charities.—St. John's Guild, New York, receives a bequest of \$3,000 under the will of the late Lillian M. Payne of this city.

A bequest estimated at about \$5,000 was left to the Stony Wold Society for the benefit of the Sanatorium at Lake Kushaqua, N. Y., by the will of the late Anna P. Morison of New York.

Crusade Against Alcohol.—On February 21 the New York City Department of Health will begin its campaign against the intemperate use of alcohol by the distribution of pamphlets in all the saloons, hotels, and clubs where drinks are sold throughout the city and by the showing of specially prepared films in the moving-picture houses. Wednesday, February 23, will be Croton Water Day and the teachers in the public schools have been requested to urge on their pupils the advantage of Croton water as a beverage over alcohol.

More Nurses for Siberia.—The American Red Cross has under consideration the sending of another party of Red Cross nurses for service in the prison camps in Russia and Siberia, where, it is said, there is urgent need for further help.

National Committee for Mental Hygiene.—The eighth annual meeting of this committee was held in New York on February 2, 1916, and was attended by a number of prominent alienists, social workers, and philanthropists. Announcement was made of a donation by the Rockefeller Foundation of \$22,800 for carrying on surveys of the care of the insane in sixteen States, this donation, together with gifts from members of the committee, making possible a

considerable extension of the work. The secretary of the committee reported that societies for mental hygiene are now active in Connecticut, Illinois, New York, Massachusetts, Maryland, Pennsylvania, North Carolina, District of Columbia, Alabama, Louisiana, and California, and that during the coming year societies will be organized in Michigan, Rhode Island, Minnesota, Indiana, South Carolina, Tennessee, and Texas. It was also stated that the financial resources of the National Committee and State Agencies have increased until now the expenditures for the work are about twenty-five times as much as in 1908, when the first society was founded.

Dr. Walter E. Fernald presented a plan for popular education, surveys, and researches on the subject of mental deficiency, saying that demands for advice regarding institutional provisions, special classes for backward children, and psychological examinations in children's courts had been received from all parts of the country. The medical director of the committee, Dr. Thomas W. Salmon, gave an account of the survey of the insane which had been carried on during the year in South Carolina and Texas, and announced that similar studies would shortly be undertaken in a number of other States. He spoke of the sufferings of the insane improperly confined in county almshouses, jails, and poor farms, and expressed the belief that the surveys made by the committee would result in the complete abolishment of this type of neglect in the next few years. Dr. Salmon reported an increase of interest in the securing for all large cities of psychopathic hospitals where early and efficient treatment for acute and recoverable cases of mental diseases can be provided. Such hospitals, with the out-patient and children's departments now exist in Boston, Baltimore, Chicago, and several other cities. New York has as yet no such institution.

At the executive session, the following officers were elected: *President*, Dr. Lewellys F. Barker; *vice-presidents*, Dr. Charles W. Eliot, and Dr. William H. Welch; *treasurer*, Otto T. Bannard; *medical director*, Dr. Thomas W. Salmon; *secretary*, Clifford W. Beers.

Semi-Centennial of the New York City Department of Health.—The Metropolitan Board of Health undertook the sanitary control in New York City and adjacent counties in March, 1866. It is proposed to celebrate this important semi-centennial by a commemoration dinner to be given on Thursday, March 9, 1916, at 7 P. M. Among the speakers expected will be his Honor the Mayor, the State commissioner of health, Surgeon General Gorgas, Dr. Walter B. James, Henry Bruere, and Dr. Stephen Smith. Subscription \$6. Acceptances and checks should be mailed to George A. Roberts, dinner committee, on receipt of which further details as to place, etc., will be forwarded.

Medical Society of the Missouri Valley.—The twenty-eighth semi-annual meeting of this society will be held in St. Joseph, Mo., on March 23 and 24, under the presidency of Dr. John P. Lord of Omaha, Neb. The Buchanan County Medical Society will act as host, and the scientific programme as so far arranged comprises two orations and twenty-five papers. Further particulars as to the meeting may be obtained from the secretary, Dr. Charles Wood Fassett, St. Joseph, Mo.

Associated Physicians of Long Island.—At the annual meeting held in Brooklyn on January 29, the following officers were elected: *President*, Dr. Dud-

ley D. Roberts; *vice-presidents*, Dr. Paul Schmuck, Dr. Lefferts A. McClelland, and Dr. William A. Hulst; *secretary*, Dr. John Cole Hancock; *treasurer*, Dr. Edwin S. Moore.

Obituary Notes.—Dr. EDGAR D. COOLEY of Port Richmond, S. I., a graduate of the College of Physicians and Surgeons, New York, in 1877, visiting surgeon to the S. R. Smith Infirmary, Tompkinsville, and a member of the Medical Society of the State of New York and the Richmond County Medical Society, died at his home from heart disease, on February 9, aged 72 years.

Dr. HENRY PARRISH of Philadelphia, a graduate of the Medico-Chirurgical College of Philadelphia in 1897, died at the home of his son, Dr. Robert T. Parrish, on February 2, aged 68 years. He was a member of the American Medical Association, the Medical Society of the State of Pennsylvania, the Pennsylvania County Medical Society, and the National Geographical Society, and a fellow of the Royal Historical Society. Until his retirement several years ago, he was laryngologist to the State dispensary for tuberculosis patients.

Dr. GEORGE I. CASON of Colusa, Cal., a graduate of the University of Missouri, Medical Department, Columbia, in 1877, and county physician of Colusa County, died at his home on January 15, aged 63 years.

Dr. WILLIAM R. EVE of Burton, S. C., a graduate of the Medical College of Georgia, Augusta, in 1867, died in Savannah on January 21. He was a member of the American Medical Association, the South Carolina Medical Association, and the Beaufort County Medical Society.

Dr. WILLIAM ALONZO ELLIS of Essex, Mass., a graduate of the College of Physicians and Surgeons, Boston, in 1906, died at his home on January 25, aged 31 years.

Dr. PHARES JAMES DUKESHIRE of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1909, died at his home from pneumonia, on February 8, aged 30 years.

Dr. RUFUS ELMER DARRAH of Newport, R. I., a graduate of the Harvard University Medical School in 1890, and a member of the American Medical Association, the Rhode Island State, and Newport District Medical Societies, and the Massachusetts Medical Society, died at his home, on February 8, aged 55 years.

Dr. JOHN C. RYERSON of Boonton, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1860, and a member of the Medical Society of New Jersey and the Morris County Medical Society, died at his home, on February 10, aged 84 years.

Dr. RICHARD CHANNING MOORE of Omaha, Neb., a graduate of the Northwestern University Medical School, Chicago, in 1865, and a member of the American Medical Association, the Nebraska State Medical Association, and the Douglas County Medical Society, died at his home, on January 27, aged 74 years. Dr. Moore was the founder of what is now the Medical College of the University of Nebraska, and was professor of diseases of the mind in that college.

Dr. SILAS ARNOLD HOUGHTON of Brookline, Mass., a graduate of the Harvard University Medical School, Boston, in 1891, and a member of the American Medical Association, the Massachusetts Medical Society, the Norfolk District Medical Society, the Boston Medical Library, the Obstetrical Society of Boston, and the New England Pediatric

Society, died at his home, February 6, after a short illness, aged 52 years.

Dr. JOHN A. DOUGLASS of Amesbury, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1861, and a member of the Massachusetts Medical Society and the Essex District Medical Society, died at his home, on February 3, aged 86 years. Dr. Douglass enlisted in August, 1862, in the Eleventh Regiment of Massachusetts Volunteers, and was honorably discharged from the United States army service in October, 1864. For many years he was a director of the Anna Jaques Hospital of Newburyport, and for some years was chairman of the Amesbury Board of Health.

Dr. JAMES B. DUNCAN of Bedford, Ind., a graduate of the Louisville Medical College, Louisville, Ky., in 1879, and a member of the American Medical Association, the Indiana State Medical Association, and the Lawrence County Medical Society, of which he was formerly president, died at his home, on January 31, aged 65 years.

Dr. DANIEL M. CAMERER of Paris, Ill., a graduate of the Rush Medical College, Chicago, in 1849, died at his home, on January 29, of paralysis, aged 92 years.

Dr. PHILIP FRIEDERICH CHRISTIAN BIEHL of San Francisco, Cal., a graduate of the Kentucky School of Medicine, Louisville, in 1883, died at the Bates Sanatorium, Berkeley, on January 30, aged 65 years.

Dr. JAMES W. GREGG of Brattleboro, Vt., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1867, and a member of the Vermont State Medical Society and of the Windham County Medical Society, died of acute angina pectoris at his home, on February 3, aged 72 years.

Dr. BENJAMIN LOTT LAMBERT of New Haven, Conn., a graduate of the New York University Medical College, New York, in 1883, and a member of the Connecticut State Medical Society and the New Haven County Medical Society, died suddenly at his home, on February 2, aged 62 years.

Dr. CARROLL R. BANCROFT of Anaconda, Mont., a graduate of the College of Physicians and Surgeons, Baltimore, Md., in 1908, city physician of Anaconda, and a member of the American Medical Association, the Montana State Medical Association, and the Deer Lodge County Medical Society, died in Los Angeles, Cal., after a long illness, on February 3, aged 37 years.

Dr. GEORGE W. COIT of Missouri Valley, Iowa, a graduate of Bellevue Hospital Medical College, New York, in 1866, died in Los Angeles, Cal., on January 30, aged 79 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

FITZPATRICK LECTURES ON MEDICINE, MAGIC AND RELIGION—ADVANTAGES OF WARMING ANESTHETICS—ROYAL COLLEGE OF SURGEONS—A DONATION—OBITUARY.

LONDON, Jan. 22, 1916.

THE Fitzpatrick lectures of the Royal College of Physicians for this year have been duly delivered by Dr. W. H. R. Rivers of St. John's College, Cambridge, who took for his subject "Medicine, Magic and Religion," abstract terms, as he admitted at the outset, each of them connecting a large group of social processes by which mankind has come to

regulate his conduct. These three groups are more or less distinct from one another. One has gone quite into the background of our social life. The other two have few elements in common, but form distinct social categories. But surveying mankind widely we do not find this separation. Among many peoples the three sets are so closely inter-related that it is difficult or impossible to disentangle them; among others, what we name medicine hardly exists, so closely is man's attitude towards disease identical with that he adopts to other natural phenomena.

The object of the Fitzpatrick lectures is the study of the history of medicine, but Dr. Rivers remarked that the study of its relations to other social processes is a necessary preliminary task, and to this he addressed himself. Time would not allow an exhaustive inquiry, so he limited himself to the field of his own researches—Melanesia, New Guinea, and slight reference to Australia. The time has gone by in sociology, he said, when we tried to understand human institutions by comparing examples from any part, and the present trend is to limit inquiries to a series of related peoples.

The distinction between magic and religion is not easy to draw, and we need a word to include both—in default of a better he used one sometimes heard, magico-religious. This implies from our point of view phenomena dealt with by supernatural means, and this implies the concept of the natural, but this is lacking among certain peoples. The essence of medicine as we now understand it is that it regards disease as a phenomenon subject to natural laws. What is the concept of those who fail to distinguish it from magic and religion? When speaking of magic, Dr. Rivers means a group of processes on which man uses rites which depend for their efficacy on his own power, or a power believed to be in certain objects and processes used in those rites; religion, on the other hand, comprises processes the efficacy of which depends on the will of some higher power, so it differs from magic by belief in a power in the universe greater than man's own. They differ in themselves by their attitudes towards man's attempt to influence the universe. On the other hand, medicine comprises whatever man tries to do to control a group of phenomena affecting himself, unfitting him for his functions, lowering his vital powers, tending towards death. These phenomena, distinguished from other natural groups, we call disease, and this concept includes the factor of causation. There are three principal classes of cause: (1) Human agency, as to which it is believed that disease is directly due to action by some human being; (2) the action of some spiritual being, or rather some non-human but more or less definitely personified agent; (3) what we call natural causes. All three beliefs are met with now, and were common in the not very remote past. By the profession and the laity alike the belief is general that the production of disease is the result of changes in our environment, independent of either human or superhuman agency. But this is not so among uncultured peoples.

In medieval magic non-human agents took a most important part, acting as immediate producers of disease and other effects, but they were held to be subjected in some way or other to the power of the human magician, and this not merely in cases of illness without any obvious antecedent, but in others which the natural cause seems obvious enough. A man's fall from a tree is attributed to a sorcerer;

so is death from a wound in battle, or a snake bite, or any event to which we should apply the term accident. Considering three main classes, the lecturer distinguished: (1) those in which a morbid agent is projected into the victim; (2) in which something is abstracted from the body; (3) in which the sorcerer acts on some part of the body of a person, or on some object which has been connected with that body, the belief being that thereby he acts on the whole person.

The advantages of warming anesthetics is, I understand, fully appreciated on your side, but it is only recently that it has attracted much attention here. Dr. Shipway, the eminent anesthetist of Guy's and the King George hospitals, has lately stated his experience and described an apparatus for the administration of the vapors. The case for warming has been pretty freely criticised, but seems to have survived the trial of experimental and clinical observations. Gwathmey investigated the effects on animals of giving the vapors in a room at a temperature of 100° Fahr., and found the plan safer than otherwise. He found it took 20.35 minutes on the average to kill seventeen animals with warm chloroform, whereas it took only 6.57 minutes to kill sixteen at ordinary room temperature. The results with nitrous oxide were similar. The heart's action and respiration were irregular during the experiment. Gwathmey came to the conclusion that warm ether vapor is twice as safe as cold, and that all anesthetics warmed to blood heat are more valuable as to life without being rendered less effective in any respect.

Dr. Shipway gives the vapor by an "open method," in which it is breathed from an atmosphere of warm ether vapor and air instead of a cold vapor through a fabric. This preserves the best points of "open ether," viz., simplicity, free respiratory exchange, and equable dosage. It is economical of ether, as less is taken in at each inspiration, a constant percentage is established, none is lost by evaporation, very little during expiration. Moreover, warm vapors are more pleasant to breathe, more readily absorbed by the blood and act more quickly and more easily render a deeper calming effect. In very hot weather the room temperature will suffice. In cold weather artificial warmth will be required to raise the vapor to 85-90° Fahr., the latter level being better for patients who are feeble or shocked, and for operations involving much exposure or loss of heat or blood. Too great heat produces sweating and flushing of the face and neck, with extra bleeding from the wound through dilatation of cutaneous vessels.

The Royal College of Surgeons have voted the sum of 50 guineas to the joint fund of the Red Cross Society and the Order of St. John of Jerusalem. They have appointed Sir G. H. Makins, who is acting as consulting surgeon to the expeditionary force in France, as the next Hunterian orator at the college.

The handsome anonymous donation of 10,000 guineas toward the cost of extensions to King Edward's Hospital, Cardiff, was announced on Monday evening.

Dr. Herbert Williams, M. O. H. for the Port of London, died after a long illness. He was one of our chief authorities on port sanitation, was born at Weymouth in 1862, fulfilled his curriculum at St. Bartholomew's Hospital and graduated M.D. London and D.P.H. Cantab. In 1892 he joined the city corporation staff at Gravesend under the port

sanitary authority. Later he was appointed to the hospital at Denton, and in 1901 succeeded Dr. Collingridge, who passed from the port office to that of M. O. H. for the city. Dr. Williams promoted or initiated a number of reforms affecting the health of passengers and crews, and improved the accommodation provided for seamen. He was formerly a major in the Royal Kent Garrison Artillery Volunteers and acted as adjutant of the corps during the South African war.

Dr. George Oliver died on the 27th ult. He was born in 1841, son of a Durham surgeon. Following his father's profession, he took M.D. London in 1873. As a student he was deeply attached to Professor Sharpey, and for a time afterward was a colleague. He practised many years at Harrogate during the season, spending the winter in London or at a pleasant country home. You will remember his device of testing with slips of paper, known now everywhere as "Oliver's test papers." His work on blood pressure is equally well known. His inventive power was remarkable. An instance, the hemocytometer and other instruments connected with his studies of the blood may be named. He founded the Oliver-Sharpey lectureship at the Royal College of Physicians, and delivered the first course, subject, "Studies on Tissue Lymph."

Progress of Medical Science.

2. Some Observations on 600 Heart Cases. Mark H. Wentworth.
3. Are There Different Anatomical Types? A Reply to Dr. Hooton. Joel E. Goldthwait.
4. Abscess of the Tongue, with Report of a Case. Joseph Penn.
5. An Operation for the Correction of the Deformity Due to "Obstetrical Paralysis." Mark H. Rogers.

1. Gun-Shot Wounds of the Soft Parts.—Beth Vincent and Robert B. Greenough give a description of these wounds and of the methods of treatment used at the American Ambulance, under the care of the Harvard Unit at Neuilly-sur-Seine, based on 318 cases. An analysis of these cases in regard to the regions involved shows that there were 24 wounds of the head and scalp, 76 of the face and jaw, 64 of the trunk, 55 of the upper extremities, and 80 of the lower extremities. Compound fractures of the jaw were of frequent occurrence, there being 63 such fractures in 76 wounds of the face. The treatment of the jaw fractures was carried out by the Dental Department of the Ambulance, by means of interdental splints, wedges, wiring, and bridging work, and very remarkable results were obtained by the ingenuity and skill of this service. The wounds were of every kind, lacerated, penetrating, perforating, or wide surface abrasions. In the treatment of these wounds the usual procedure was as follows: The patient was given a general anesthetic, the skin was shaved, painted with iodine, and the wounds enlarged as much as the extent of the infection required; the crushed edges of the wound of entrance and all necrotic tissue were excised; all the foreign material, such as dirt or particles of clothing, was removed. Some wounds were irrigated and some were simply wiped dry. Drainage was accomplished by means of cigarette wicks or drains made of folded rubber tissue. Raw surfaces were covered with sheets of rubber tissue. The use of rubber tissue for wicks and as protective covering, saved the patients much suffering. The most septic wounds were given continuous irrigations of sodium hypochlorite solution (1:200), others had frequently

changed wet dressings, but most of the cases were dressed with plain sterile gauze. Even the very septic cases did surprisingly well, due, in part, to the good general condition of the French soldiers, and in a large measure to the skill and care with which they were treated by the house staff. A well balanced unit needs, for such work as this, comparatively few surgeons to do the operations, but should have a large number of well trained men to look after the patients in the wards. In the location of foreign bodies the means most used at the American Ambulance were the fluoroscope, x-ray plates, and the Bergonier electro-magnet. For routine work the fluoroscope proved to be the most rapid, accurate, and economical means of locating lodged missiles.

2. Some Observations on 600 Heart Cases.—Mark H. Wentworth writes that between March, 1912, and May, 1914, he assembled at the Boston Dispensary 600 cases of children between the ages of six weeks and fifteen years with one or another form of heart weakness, rheumatism, or chorea. Of the whole series there were but 30 which had rheumatism not followed by a heart disturbance of some sort, and most of these were admissions of comparatively recent date. This series was carefully tabulated with reference to the character of the heart lesion and its etiology. Of all the cases in the series, 270 were apparently caused by rheumatism or tonsillitis, 82 by acute infectious diseases. The etiology was undetermined in 239 cases. The writer finds that children are far more liable to attacks of rheumatism than others, recurring attacks are more frequent in them, and cardiac involvement following rheumatic infection is more frequent. He doubts the wisdom of always recommending the removal of the tonsils and seldom advocates it except in cases which have had marked recurring attacks, or in which it is evident from the past history that the child is subject to tonsillitis. Two hundred and fifty-seven observations were made on the blood pressure, an effort being made to see how it was influenced by rest, and by rest and tincture of digitalis medication. In the cases in which no drug was used, the patients having simply stated periods of rest and supervision of their hygiene, the effect upon the systolic pressure showed nothing striking, though there was a tendency to a slightly rising pressure. Under the influence of digitalis, which was combined with rest, the results on the systolic pressure showed a much greater and more uniform tendency to rise. The diastolic pressure when treated with digitalis showed much the same readings as when the patients were given rest only. Digitalis should not be used with a free hand or indiscriminately. Its action should be carefully watched. Where no appreciable effect is noted on the pulse, one should examine the heart and general circulation before increasing the dose. In cases showing degeneration of the heart muscle digitalis may be absolutely contraindicated. In cases of tachycardia the writer has found that minute doses of aconite or strychnine may be used to better advantage than digitalis in reducing the accelerated pulse.

5. An Operation for the Correction of the Deformity Due to "Obstetrical Paralysis."—Mark H. Rogers describes an operation for the correction of the deformity which usually follows brachial paralysis occurring at child-birth which has been in vogue in Germany and has been described by Vulpius and Lange, and reports a case in which he has performed this operation. The operation is simply an osteotomy of the upper portion of the humerus about two inches below the shoulder joint, followed by a one-quarter rotation of the whole arm below the line of fracture. An incision is made between the muscle planes sufficiently long to be sure

that there is no nerve involvement. A clean cut osteotomy is done, and before the incision is closed the arm is brought out at a right angle to the body and the lower fragment is rotated outward, while traction is kept on the hand. The tip of the finger is held on the fracture to see that there is no overriding and that the position is good. The wound is closed and the arm and body are encased in a shoulder spica with the arm full-length at right angles and the palm of the hand pointing upwards. It is then treated as an ordinary fracture. The results of the operation are a normal carrying position of the arm, with the elbow at the side, and a normal position of the hand.

2. The Prompt Cure of Gonorrhea. George A. Wyeth.
3. Criminology from the Standpoint of a Psychiatrist. Morris J. Karpas.
4. Pollutions in the Male. Max Hühner.
5. Bronchiectasis from the Standpoint of the Bronchoscopist. Sidney Yankauer.
6. A Case of Eclampsia. Albert Comstock.
7. Meningeal Hemorrhage in the Newborn. Maurice J. Lippman.

1. Acute Appendicitis.—John B. Deaver says the important points that have to be learned about this disease are that it is the most common intraabdominal inflammation; that indigestion is often a forerunner, preparing the soil for the infection; that being an infectious disease and the most common infectious disease of the abdominal cavity, the appendix constitutes the avenue by way of which infection most commonly invades the upper abdomen. He considers acute appendicitis from the anatomical, etiological, bacteriological, and pathological standpoints; the points of the latter touched upon chiefly are in connection with peritonitis and abscess. The portions of the peritoneum most susceptible to infection are the diaphragmatic and enteronic. The differential points between a diffuse and a localized peritonitis are that in the former the pain is greater, the abdominal breathing more restricted, and the rigidity and tenderness embrace a greater area of the overlying abdominal wall; upon auscultation the peristaltic waves are heard over a greater area and the abdominal breathing is less marked in the diffuse than in the localizing variety. In the early stages the tenderness and rigidity are best elicited by slight pressure. If the symptoms and signs, namely, pain, vomiting, fever, tenderness, and rigidity are interrupted, the diagnosis of acute appendicitis may be considered doubtful. Leucocytosis is of value as a confirmatory symptom when the patient reacts well to the infection. The most important point in the differential diagnosis is the distinction between acute cholecystitis and acute appendicitis. Acute pancreatitis, perforated ulcer, or perforated gall bladder, present symptoms so much more intense than those of acute appendicitis that they should not give rise to confusion. As to the treatment, the writer states most emphatically that in all cases of acute abdominal pain nothing in the shape of a purgative or aperient medicine should be given until the cause of the pain is understood. In his experience purgatives play the greatest amount of havoc in acute abdominal conditions; 90 per cent. of cases of perforating peritonitis have been purged. In the presence of peritonitis and in the absence of operation the patient should be set up in bed, given nothing by mouth, not even cracked ice; he should be given enteroclysis by the Murphy method and have an icebag over the site of rigidity and tenderness; the icebag is useful to prevent the doctor from making too many examinations and for its local anesthetic effect. The idea that it has any effect in controlling inflammation is fallacious. In

diffuse peritonitis, in the absence of peristalsis and of a definite point of localization, it is the writer's practice to defer operation until the peritonitis becomes a localized or localizing one. The principles of anatomical and physiological rest, assisting the functions of the peritoneum, absorption and exudation, are defeated by any treatment other than the foregoing.

2. The Prompt Cure of Gonorrhea.—George A. Wyeth, after reviewing the pathology of gonorrheal invasion, states that if a patient is seen within twenty-four hours after a pus discharge has begun a cure can be effected in 60 per cent. of the primary cases within six or seven days, leaving the patient free of gonococci and all discharge, with urine clear and able to withstand all provocative tests. Since in the early stages of gonorrhea nature's mode of fighting gonococci is by phagocytosis, the indications in treating this disease are to employ remedies which, first, stimulate leucocytosis; secondly, act as mild gonococcocides, and thirdly, cleanse thoroughly the urethra without injury to the tissues. Thus, the aim is to increase the discharge, and not to check it as has been the time-honored custom. In the writer's experience, after much experimenting, chemically, bacteriologically, and serologically, these indications are best met by the use of protargol, in a 0.25 to 0.5 per cent. solution, or of any mild therapeutic agent which fulfills the indications. In a 2 per cent. solution it is astringent and in this strength is to be avoided as long as gonococci are present. The anterior urethra is flushed with 300 to 450 c.c. of the solution of the strength above mentioned, and successive flushings are continued until the whole amount of solution is used, always with care that no undue pressure is exerted. The patient is instructed how to inject the urethra himself every four hours. On the second day the initial treatment is repeated. After the third day, if no gonococci are found, the frequency of the injections is decreased. No internal medicine is given and no diet regulation attempted beyond the interdiction of alcoholic drinks and highly seasoned foods. In cases in which a cure is not realized in six or seven days, by continuing this treatment the duration of gonococcal infection can be limited to from three to six weeks instead of the usual six weeks to three months.

3. Criminology from the Standpoint of the Psychiatrist.—Morris J. Karpas emphasizes the point that crime is an expression of maladjustment, and in a large majority of instances, the instinctive life or the unconscious is the determining factor. The more complex the social organization, the greater the number of crimes, because adjustment in such communities presents some difficulty. The writer considers criminals under three groups: (1) Casual, environmental, or social; (2) constitutional or habitual; (3) symptomatic. He urges that our present treatment of this class must undergo a radical change. A person who has been subjected to a number of repeated attacks of crime should be declared irresponsible and placed in an artificial environment fitted to his peculiar mental make-up, where his energy may assume a constructive tendency rather than make him a subject of dependency and humiliation. A more hopeful way of attacking this intricate task would be to turn our attention to the study of the juvenile delinquent since the juvenile delinquent is the father of the habitual criminal.

4. Pollutions in the Male.—Max Hühner distinguishes between normal and pathological pollutions and states that for the latter no treatment succeeds so well as bromides in large doses. He prescribes 15 grains of sodium bromide three or four times a day, well diluted, after meals. The primary effect of this treatment is remarkable and the psychic effect of the rapid diminu-

tion of the number of pollutions is also well marked. At the same time the congestion or other pathological condition in the posterior urethra must be relieved. For this purpose the writer has found the instillation of weak silver solution through the Bangs sound syringe to be most efficient. The strong cauterization of the verumontanum, as recommended by German authorities, he has found of no use whatever. As a prophylactic against pathological pollutions boys approaching adolescence should be instructed as to the harmlessness of normal pollutions and advised to abstain from alcoholic beverages, tea, coffee, and erotic thoughts.

1. Conservation of Vision and Prevention of Blindness.—G. E. de Schweinitz believes it safe to say that fully 100,000 men, women, and children in this country are, within the strict definition, blind; one-fourth of these need not have lost their sight. About 25 per cent. of the inmates of schools and asylums for the blind have lost their sight from ophthalmia neonatorum. The writer considers the measures devised and in operation for the elimination of this preventable cause of blindness, namely, education, compulsory notification, the punishment of offenders against properly constructed legal regulations, and compulsory prophylaxis. Of these compulsory notification represents the most effective method at our command, since a notification which should go at once to a legally qualified physician can quickly command the services of some one skilled in the treatment of ocular disease. The National Committee for the Prevention of Blindness should insistently urge that hospitals accepting State aid should make provision for the care of cases of ophthalmia neonatorum. This should be done not only because it is a real work of humanity, but also because it would mean a reduction in the number of blind and therefore a lessening of the economic loss to the commonwealth. The ravages of ophthalmia neonatorum have been so conspicuous that there has been a failure to recognize the importance of trachoma and glaucoma causing blindness. The writer believes that the work of a national committee for the prevention of blindness should not be concerned alone with the prevention of blindness in the strict sense of that term, but ought to be concerned with the elimination of the evils which spoil eye efficiency and suggests that a national committee such as the one in existence should have a subcommittee entirely concerned with the important question of illumination. Finally, in discussing schools for the blind, and partially blind, Dr. Schweinitz expresses the opinion that much could be gained by a sensible application of the principles of modern psychological research, since an investigation of this character would help in the classification in accordance with the need of the case of each child.

2. Syphilitic Aortitis.—Douglas Symmers and Guy H.

Wallace state that the mesaortitis of Heller and Döhle is essentially a syphilitic lesion, but its production is favored by certain other factors, among which age, sex, the length and character of antisymphilitic treatment, intercurrent disease, especially infections such as acute rheumatic arthritis, alcoholism, and occupations necessitating prolonged physical strain, play a not unimportant rôle. Syphilitic aortitis occurs most often in males, having been found in 80 per cent. of their series. This is a fact which assumes additional importance when taken in connection with occupational influences. Syphilitic aortitis is a lesion of comparative youth, occurring oftenest between the ages of thirty and fifty years, having been found at this age period in 71.4 per cent. of their cases. In untreated or neglected syphilis the average interval between infection and death with anatomical confirmation of the existence of syphilitic aortitis is 20.5 years, from which fact it is apparent even in the least favorable circumstances the lesion rises late in the course of syphilis. About 30 per cent. of all patients with syphilitic aortitis develop aneurysm. At least 15 per cent. of all cases of syphilitic aortitis are attended by dilatation of the first portion of the aorta. About 30 per cent. of all cases of syphilitic aortitis eventuate in sclerosis and retraction of the aortic valves. Leaving out of consideration the occurrence of such clinical phenomena as angina pectoris and cerebral disturbances referable to occlusion of one of the larger branches of the aorta it appears to be probable that few cases of syphilitic aortitis pursue a course free from subjectively appreciable or even detectable clinical manifestations.

3. Reactions and Results of Treatment in Cerebrospinal Syphilis.—George Draper has made observations on thirty-eight cases, watched over periods of from three months to three years. These thirty-eight patients were given 1,126 intravenous injections and 355 intraspinal injections of medicated serum, the technique of administration being the usual one. He found that the severest reaction to intravenous injections was of the anaphylactic type. The most frequent reaction to the intraspinal injections was pain. The severest was an aseptic meningitis, which might have been anaphylactic in origin. Twenty-six patients out of the total of thirty-eight were economically useless before treatment. After treatment twenty-two were back on full-time work. The rapidity and the degree of improvement depended directly on the intensity of the treatment. It is important to keep the patients at work during the months of treatment.

4. Intraspinal Administration of Mercurialized Serum in the Treatment of Syphilis of the Nervous System.—Edward Livingston Hunt presents a record of work done at the City Hospital on Blackwell's Island, New York, where they have been trying the intraspinal administration of mercury. The cases treated were forty-five in number; forty were given intraspinal injections of mercuric chloride, and five were given sublamine injections. These patients were at the same time given intramuscular injections of mercuric salicylate every week, and in the very early ones intravenous injections of salvarsan. The cases treated comprised cases of tabes, general paresis, cerebrospinal syphilis, taboparesis, clinical tabes (tabes with a negative serology), and syphilitic hemiplegia. The writer concludes as follows: 1. The reaction from mercuric chloride or sublamine in no way differed from the reaction which followed the administration of salvarsan. 2. The sublamine did not seem to give the same reduction in the cell count or clinical improvement as did the mercuric chloride. 3. No ill results followed these injections. The three deaths could be easily accounted for, as the patients were practically moribund at the time of the treatment, and were

given the injections as a last resort. 4. The patients with tabes and cerebrospinal syphilis were helped more than any others. 5. Such improvement as did occur was evident in the feelings of the patient, in the sphincter control, in the pains, in the gait, and in the serology. There was no improvement in the reflexes. 6. Such intraspinal treatment can be given only at intervals of two weeks, because a cell count does not fall sooner. 7. The reaction obtained was one in which the cell count was first greatly increased, and then diminished. 8. The cell count and the globulin yielded much sooner than did the Wassermann.

5. Selective Regeneration in an Ulnar Nerve Lesion.—Isador H. Coriat reports a case which offers evidence of the independence of the sensory nerve endings of the skin as demonstrated during regeneration of the ulnar nerve. The patient was accidentally cut with glass on the left wrist, completely severing the ulnar nerve. After about two months the nerve was sutured. Six months later examination shows that the ulnar side of the left hand is the seat of severe tingling and, at times, pain. It is decidedly hyperalgesic to various stimuli, such as rubbing, touching, etc. The little and ring fingers are glossy and mottled. All the muscles innervated by the ulnar nerve are weak and atrophied. Isolated pain points can be demonstrated in a completely anesthetic area, while inside this area the pain points are so closely crowded together that they form a zone of extreme hyperalgesia. Deep sensibility is intact. This condition proves that the specific receptors for pain are not only independent but also are more capable of rapid regeneration than the specific receptors for touch. The condition is best termed a selective sensory regeneration.

6. Exstrophy of the Bladder.—James J. Moorhead and Edward L. Moorhead report two cases of exstrophy of the bladder, a condition which they state occurs about once in 29,000 births. The first case was in a male, and a modified Maydl operation was performed. The patient died a week afterward and a limited post mortem revealed a circumscribed peritonitis in the region of the transplantation. Venous thrombosis was present in the region examined and pulmonary embolism was probably the immediate cause of death. The authors believe that development of the technique of this operation on lower animals is essential to success. The second case was unique in that, according to the literature, it was the first in which the patient was a mother. Childbearing had been followed by prolapse of the uterus and vagina. The patient was operated on in two stages. At the first operation the cervix was amputated and the pelvic floor repaired. Three weeks later a modified Maydl operation was performed. This patient left the hospital in five weeks, at which time urine was retained four hours during the day and caused her very little discomfort at night.

8. Index of Urea Excretion.—Franklin C. McLean presents a relatively simple method, based on the laws of Ambard, for the direct quantitative determination of the state of the function which has to do with the elimination of urea. He finds this method applicable in a wide range of cases, easy of performance, and giving results which should prove of great value in the recognition, prognosis, and treatment of certain conditions associated with impairment of the renal function.

2. Bactericidal Power of Serum.—S. R. Douglas and L. Colebrook find that neosalvarsan and salvarsan in watery solution possess a very distinct bactericidal power against staphylococcus when the strength of the solution is 1 in 6,000. When the solvent largely consists of blood or serum this power is slightly diminished. The bactericidal power of solutions of both these preparations appears to be practically the same. The administration of neosalvarsan in ordinary doses renders the blood fluids markedly bactericidal. This power lasts but a short time and seems to reach its maximum about one hour after the administration of the drug, diminishing rapidly after the third or fourth hours. Heating the serum to 60° C. for ten to twenty minutes has no deleterious effect on this bactericidal power, showing that it is not in any way due to the development of immune bodies in the serum, and this fact together with the short period in which the serum is found to be bactericidal strongly suggests that the bactericidal power is due to some arsenic compound in solution in the blood serum. Salvarsan, which has almost the identical bactericidal power as neosalvarsan *in vitro* experiments, gave practically no demonstrable bactericidal power to the patient's serum when ordinary therapeutic doses were administered; but organisms which had been treated with the serum obtained within three hours of the administration of the drug grew very much more slowly than normally and were agglutinated into masses. The author voices the hope that the administration of neosalvarsan, or some similar preparation, would have a beneficial effect on wound or other septicemias and might assist in the sterilization of deep and irregular suppurating wounds.

3. A Contribution to the Biology of the Vermiform Appendix.—W. Colin MacKenzie has made a study of the two monotremes and the various marsupials of Australia which he has found offer a unique opportunity in aiding the solution of many important biological questions, and especially those pertaining to the gastrointestinal tract. He finds the biological teaching decidedly against the inutilty of the large intestine. It is also noteworthy that the ultimate disappearance of the appendix is a coordinate action and not necessarily associated with such frequent inflammations as we are witnessing in the human type. Although a large number of wombats has been examined in no one case has any evidence of inflammation been seen, nor has the writer as yet heard of an instance. In the case of man the question arises: What is the factor interfering with proper coordination? Is the leakage dietetic, or is it a question of environment or due to the erect posture? The author says we can scarcely expect surgery to give the reply.

4. Notes on Friedländer's Pneumobacterium.—A. R. Friel calls attention to the fact that Friedländer's pneumobacterium which is present as a general rule in cases of ozena, is usually very resistant to phagocytosis. However, these bacteria can be phagocytized, and in large number, by using the serum of a rabbit which has received two or three intravenous injections of a living or killed emulsion of the Friedländer organism. This serum is so active that the bacteria are agglutinated and opsonized, and if left long enough (one hour) in contact with the serum are dissolved. To prevent the bacteriolytic action of the serum taking effect, it can be heated to 56° C. for half an hour. If one volume of the Friedländer

organism be mixed with five or six volumes of inactivated immune serum and allowed to stand for three to five hours at the room temperature, and if the clump of bacteria which has then formed be removed and washed in salt solution and planted on a sloped agar culture tube, a good growth will have taken place by the following day. If this process is repeated for a few days it will be found that a marked change has taken place in the bacterium, and this change is preserved for several subcultures without further treatment with immune serum. The bacterium can now be slightly agglutinated and readily opsonized by ordinary human serum. In treating patients suffering with ozena, the writer finds that to get rid of the Friedländer infection it is advantageous to give the vaccine intravenously, and he is in the habit of using as a dose two million of a sensitized non-sterilized emulsion in salt or distilled water, which is injected into a vein at the bend of the elbow or in the forearm. He also presents as an explanation of why an intravenous injection of the Friedländer bacterium is superior for purposes of treatment to the subcutaneous one that it may be that for the production of some immune bodies an internal organ such as the liver is an essential factor, and if the vaccine is given intravenously the production of immunity is more rapid than by cutaneous injections.

6. Sodium Hypochlorite in the Treatment of Septic Wounds. Frederick J. A. Dalton.

1. The Soldier's Heart.—James Mackenzie, who has charge of an inquiry into disorders of the heart for the medical history of the war, has been associated with Dr. Wilson and together they have examined 400 cases. They find that 90 per cent. of the cases that have been certified and treated as heart affections were not primarily heart cases, and that the principles applicable to these cases are widely different from those applicable to cases of heart failure. The signs and symptoms in these cases are great vasomotor instability, a sense of fatigue and exhaustion, breathlessness on moderate exertion, more infrequently pain over the region of the heart. The heart's rate is often not increased; in some it is persistently increased. Murmurs, systolic in time and heard in different regions, are frequent, while an increase in size is not at all uncommon. Irritability and depression are frequently noted. This condition is brought on by the strain of life in the trenches or may be the reaction of the heart to toxin. In the treatment of these cases the patients are encouraged to take moderate exercise so long as it gives them pleasure and causes no distress or discomfort, but to stop or slow down as soon as a sense of exhaustion, breathlessness, or pain is experienced. The writer suggests that this view of the nature of the soldier's heart should be communicated to the medical officers, in order that the diagnosis should be in conformity with the actual condition, and in this way prevent the grievous injury that is done to the sick soldier by implanting in his mind the depressing idea that he is suffering from an affection of the heart.

3. Vascular Phenomena of Cardiac Disease.—Basil Parsons-Smith emphasizes the fact that considerable importance should be attached to a complete investigation of the blood vessels in all cases of heart disease. He suggests that venous auscultation be not forgotten,

for by its aid one gains additional advantages, abnormal sounds become audible; for instance, the well known *bruit de diable*, characteristic of anemic states which, caused by loss of tone in the vein walls, is heard best when the patient is in the standing position, also the upwardly conducted vena-cava murmur, the sounds resulting from the closure of the venous valves, and, lastly, the clicking sounds to which the rapidly contracting auricle of auricular flutter gives rise. One should listen specially for the normal second aortic sound in the neck of patients with aortic incompetence; also ascertain if the murmur is conducted into the vessels, its relative loudness in this situation and at the aortic cartilage, and should base his prognosis upon the results of such an examination, combined with the ordinary careful physical examination.

4. The Heart's Action in Jaundice.—J. Davenport Windle has investigated the heart's action in a number of jaundiced patients; in some he has found the pulse infrequent, in some irregular, in others both infrequent and irregular, but he has not been satisfied in any case that the jaundice was responsible for the infrequency or the irregularity. He says it has been stated that the pulse may fall as low as 40 a minute; if by "pulse" is meant rate of ventricle, this rate he finds must be rare, for he has not met with one instance in over 100 cases of jaundice. A pulse rate of 50 to 55 per minute is not uncommon in patients with jaundice when free from fever and the patient is kept in bed, but this is not proof that the jaundice is the cause of the slow pulse. In a number of cases the writer has found a pulse rate of 40 and below; but the heart rate has been double the pulse rate, the infrequent pulse being due to an alternate premature beat of the ventricle too feeble to send a wave to the wrist. His experience indicates no proof that patients with jaundice are more liable to develop extrasystoles than are patients suffering from other toxic conditions. All the cases of jaundice with premature beats which the writer has met have occurred in persons past middle life. Irregularity due to extrasystoles may be favored during jaundice, but it is not, in the opinion of the writer, because of any action of the bile salts on the cardiac muscle, but because the illness keeps the patient resting. In catarrhal jaundice there is usually fever with rapid pulse before the jaundice appears; when the jaundice comes out the fever goes and the pulse rate falls. The writer has observed no case of heart block during jaundice.

6. Sodium Hypochlorite in the Treatment of Septic Wounds.—Frederick J. A. Dalton submits the report of the committee sent to the Gallipoli peninsula to make observations on the efficacy of hypochlorites in the treatment of infected wounds. This report describes the preparation of the hypochlorite solution, the methods of use, cites a number of cases, and concludes that the advantages observed in the use of the sodium hypochlorite solution in the treatment of septic wounds are as follows: 1. The simplicity and cheapness of preparation of the antiseptic. 2. Being non-toxic and non-irritating to the tissues when properly prepared according to Dakin's formula, the hypochlorite solution may be safely used in large quantities over long periods of time without ill effects. 3. The deodorant action of the solution is remarkable. The fetor from gangrenous tissues usually disappears in twenty-four hours. 4. The rapidity with which sloughs separate and clean granulation tissue is formed in a wound under its influence. 5. The infrequency of redressing required by cases treated as described with hypochlorite, compared with the constant change of dressings required in large wounds with other forms of antiseptic. 6. The fact

that injections of the hypochlorite solution into the rubber tubes used in the dressings may with safety be entrusted to very imperfectly trained orderlies without fear of ill results, once the case has been adequately dealt with by the surgeon.

Berliner klinische Wochenschrift.

December 27, 1915.

What Will Be the Future Attitude of Germany Toward Foreign Drugs?—Lewy refers first to the so-called elegant pharmaceuticals prepared in France. These include articles dispensed as "pearls," "dragés," "cachets," etc., which command a high price. The menthol preparations had a large following in Germany and were kept in the hospitals. German imitations even when sold at a much lower rate cannot supplant these imported articles. Two famous French antiarthritic mixtures, despite the publication of their formulæ for the benefit of druggists, belong under this head. Moreover, some of these French preparations are misrepresented. There is a great demand among nervous women for a high sounding proprietary which is evidently only a coal tar sedative, perhaps the very one which it apparently seeks to supplant. The Bulgarian bacillus remedies have a strong demand in Germany. One is cited which contains only podophyllin. Various arsenicals (cacodylates) are not as represented. Coming now to England, we find compressed tablets and tabloids the chief vehicle for medicaments because they can readily be shipped to the various parts of the empire. These have been used extensively in Germany for twenty years and are not to be confounded with synthetics. Their success has been remarkable, yet the best sellers are of very simple formulæ, not private. The tremendous patriotic movement at the beginning of the war to drive out all of these old popular favorites has not been entirely successful. The old proverb, "the German hates the Frenchman but loves his wines," might be rewritten to include French and English proprietary medicines. Foreign cosmetics and nutrient preparations are more or less "quacked" in Germany through preposterous claims as to efficacy. Organotherapeutic preparations of French, English, and even Russian origin sold largely in Germany before the war. At present France is endeavoring to prepare against a flood of German preparations after the war is over, but the author is certain that all people will buy medicine without regard to sentiment. The great importing drug houses do not propose to lose their business and are not friendly to the idea of domestic substitution. Again many manufacturers have branch factories in foreign countries. Substitution may be good in a way for Germany but it is not strictly a business proposition, and business will always be business.

Removal of a Large Orbital Tumor with Sparing of the Eye Ball.—Halben reports a case which may be unique. The growth removed was a fibrosarcoma as large as an apricot. While it filled the orbit, thrusting the eye forward, it proved to be nowhere adherent, either to the bone, optic nerve, or muscles. Nevertheless compression of the orbital wall had diminished their resistance. The optic nerve was flattened against the nasal wall. Krönlein's technique was used to enter the orbit. The growth was in contact with all the orbital walls but was readily enucleated with the finger. The extraction was strikingly like delivery of the fetal head in labor and was followed by a gush of blood. There was complete amaurosis but the ophthalmoscope showed that the fundus was normal. In a few days the patient was able to count fingers.

Münchener medizinische Wochenschrift.

December 28, 1915.

Acute Yellow Atrophy of the Liver After an Accident.—Curschmann states that his is the third recorded case of this association. The patient was a child two years of age and of good antecedents, although he had rickets of moderate degree and had had teething convulsions. When stricken with the liver affection his condition and mental disposition had been good up to the time of the severe fall across the back of a chair. He struck squarely over the abdomen and ecchymoses developed. Nevertheless he continued to climb until he had a second accident the counterpart of the first. In from 2 to 3 days afterwards, he showed a subicteric tint on the conjunctivæ, but went about as usual. Five days after the accident he began to vomit bile and displayed more jaundice. For two days more he was able to play but now developed a delirious attack which was the first evidence of serious mischief. This soon ended in unconsciousness. The full picture of jaundice was now in evidence. At the hospital the chest finds were normal. The abdomen was also normal but percussion showed that normal hepatic dullness had almost disappeared. The nervous system aside from loss of consciousness seemed absolutely intact. The chief finds, aside from the small liver and jaundice, were moderately high fever and rapid, feeble pulse, and the urinary symptoms (leucin crystals present although as tyrosin). The diagnosis—and prognosis—was only too obvious. Death took place in coma, preceded by restlessness and temperature rise. The liver weighed about half a pound only. The microscope showed that it was almost completely necrotic. In theory the trauma must have started up some latent infectious or toxic process. The published reports of the two other (Italian) cases of traumatic acute atrophy of the liver were not accessible to the author, but, as far as his recollection went, they were set down to the activation of an infectious process. The most plausible supposition is a latent congenital lues, although no suggestive history was obtainable, and unfortunately the Wassermann reaction was not employed.

Red Vision after Eating the Seeds of the Solanum Dulcamara of Linnaeus.—Hilbert while on military duty was summoned to treat a village child, a girl 8 years old, who had become violently ill after eating red berries the presence of which was evident in the vomitus. The child was very restless, complained of pain in the head and stomach, vertigo, palpitation, and anxiety. She also insisted that "everything looked red" like the color of the berries she had eaten. The patient's face was reddened, pupils widely dilated, so that reading was impossible. The skin was dry; pulse 120, occasionally intermittent. As there was no stomach pump available the child was made to drink warm water until the vomitus came away clear. After a draught of cold milk the gastralgia abated and the child fell asleep. Next day she was pale and depressed, pupils still dilated. The red vision was no longer complained of. In about 5 days she was quite restored. The toxic effects are to be ascribed wholly to the solanin in the berries which is closely related to atropine, scopolamine, duboisine, hyoscyamine, and datune. All these alkaloids are nerve poisons, mydriatics, and paralyzers of accommodation. Both atropine and duboisine have been known to cause red vision. We know nothing, however, Hilbert said, of the intimate chemical constitution of either of these bodies. Fortunately for the child, not more than a dozen of the berries had been swallowed. The author had no antidotes at his disposal, not even morphine or tannic acid.

Deutsche medizinische Wochenschrift.

December 23, 1915.

Action of Hypophysis Extracts upon Graves' Disease and Hyperthyroidism.—According to Pal hypophysis extracts have no effect upon the normal thyroid gland and certain strumas. But when given for the thyrotoxicoses, the toxic state improves. Even if the gland is increasing in size improvement is noted. This increase in size is evidently due to distention of the follicles, so that the toxic secretions of the thyroid must have a separate origin and be antagonistic to the active principle of the follicular substance. The author has used hypophysis extract in 16 cases of Graves' disease and hyperthyroidism. The reaction was not the same in all cases. The remedy was first given internally. Although one surprising result was thereby obtained he proceeded to use the hypodermic method. Finally his chief interest was absorbed in the cachectic cases with low blood pressure, and showing every token of deep intoxication. In nine such cases in which an operation could not be performed, he obtained a gain of weight in seven. There was also improvement in restlessness, tremor, and outbreaks of perspiration. The tachycardia showed a gradual improvement, but returned as soon as the medication was suspended. In three of these severe cases was seen especially the paradoxical symptom already mentioned—swelling of the thyroid; and in a fourth case of apparent atrophy of the thyroid with profound thyrotoxicosis, the latter was not only overcome but the patient acquired a new thyroid and there is no doubt that his life was saved by the extract. Animal experiment has shown sufficiently that thyroid and pituitary extract are in part antagonists—for example in their action on the circulation; and the author assumes that the latter also inhibits the secretion of the former. At the same time some antagonistic substance normally held in check by the thyrotoxic substance appears to be generated in excess and to produce swelling of the gland.

Treatment of Pyodermatoses of the Lower Extremities in the Field.—Strauss refers to the frequency and obstinacy of these lesions in the troops. These baffle sufficiently the dermatologist while the regiment surgeons find the problem correspondingly greater. At the outset the lesions are mild, and there is no general reaction and the surgeon dislikes to retire the victims for treatment. Hence the importance of a satisfactory early management. The rationale is simplicity itself. The soldier cannot care properly for his lower extremities which accumulate dirt. He cannot change his underwear and socks, and one result of this status is itching, which leads to violent scratching and traumatism. The ordinarily innocent staphylococcus becomes pathogenic and different types of suppuration result, including folliculitis. Boils do not result, but large, infected excoriations form and develop crusts which when removed reveal a bleeding corium. These superficial ulcers show very little tendency to heal but develop readily into ecthymatous lesions. As a result various suppurations which differ in kind and degree tend to multiply—a certain predisposition is at times in evidence—until a serious, disabling condition is present. Reinfection is doubtless an active factor. The treatment is simple but any treatment is difficult to carry out. Soap and water, with benzine frictions bring about mechanical sterilization. All foci of suppuration should be exposed and all raw surfaces treated with an ointment which consists chiefly of silver nitrate and Peruvian balsam. Very hairy limbs, varicose limbs or an unusual degree of inflammation furnish special indications.

Book Reviews.

TEXT-BOOK OF NERVOUS DISEASES, FOR THE USE OF STUDENTS AND PRACTITIONERS OF MEDICINE. By CHARLES L. DANA, A.M., M.D., LL.D., Professor of Nervous Diseases in Cornell University Medical College; Consulting Physician to Bellevue Hospital; Neurologist to the Montefiore Hospital; Neurologist to the Woman's Hospital; Consulting Physician to the Manhattan State Hospital; ex-President of the American Neurological Association; ex-President of the New York Academy of Medicine; Corresponding Member of the Société de Neurologie, etc. Eighth Edition. With 262 Illustrations, including 4 plates in black and color. Price, \$4.25 net. New York: William Wood and Company, 1915.

THIS is the best of eight editions of a standard text-book on nervous diseases by an American author. The volume is considerably smaller than the seventh edition, due chiefly to the omission of former detailed chapters on anatomy and on therapeutics, and of the part devoted to mental diseases. Special anatomical descriptions of the nervous system are not now required, in the judgment of the author, in text-books on nervous diseases, owing to the great improvement of late years in these descriptions in the anatomical text-books. The same remark applies to neurological therapeutics as described in special treatises. The part devoted to psychiatry is promised later in a separate volume. A chapter on paresis and articles on some of the minor psychoses, however, are retained in this volume. Several chapters throughout the book have been revised and rewritten, largely owing to recent discoveries and advances in neurological science and practice. Such revision is noted in the author's descriptions of diseases of luetic origin; also in special chapters, by collaborators, on anterior poliomyelitis, on epidemic cerebrospinal meningitis, and on spinal and brain tumors. The chapters on diagnosis and on disturbances due to glandular disorders, and some other chapters have also been rewritten. The psychoanalysis of the Freudian School the author does not apparently subscribe to; but he states that he has given it "a place in the interpretation and occasionally in the therapeutics of the minor psychoses."

One or two of the rarer nervous diseases, *e. g.* family periodic paralysis, have for some reason, been omitted. On the whole the improvements in the present edition bring the book down to date and increase its value and should enhance its popularity both as a book of reference and as a text-book for students.

DISEASES OF THE SKIN AND THE ERUPTIVE FEVERS. By JAY FRANK SCHAMBERG, A.B., M.D. Professor of Dermatology and Infectious Eruptive Diseases in the Philadelphia Polyclinic and College for Graduates in Medicine; Dermatologist to the Philadelphia General Hospital, the Jewish Hospital, and Samaritan Hospital; Fellow of the College of Physicians of Philadelphia; Member of the American Dermatological Association. Fully Illustrated. Third Edition Thoroughly Revised. Price, \$3.00. Philadelphia and London: W. B. Saunders Company, 1915.

BY far the largest part of this handsome volume has appeared in the author's well known "Compend of Skin Diseases." To this is added an important section on Acute Eruptive Fevers. The present edition contains new chapters on the value and interpretation of the Luetin Test in Syphilis, and on Rocky Mountain Spotted Fever; the chapters on Therapy of Syphilis and on the mild type of Smallpox have been amplified and brought up to date. The book is well printed and adequately illustrated, and should prove of considerable service to the general practitioner. The inclusion of the Exanthemata in a work on Skin Diseases is an important feature, and one which cannot fail to be appreciated by every reader.

THE GYNECOLOGY OF OBSTETRICS. An Exposition of the Pathologies Bearing Directly on Parturition. By DAVID HADDEN, B.S., M.D. Fellow of the American Association of Obstetricians and Gynecologists. Fellow of the American College of Surgeons. Price, \$3.50. New York: The Macmillan Company, 1915.

In this volume the author shows the importance of perineorrhaphy and trachelorrhaphy; and emphasizes the fact that while they may be classed (surgically) as minor operations, they are of the utmost importance to

the happiness and physical well being of the patients. Another feature of the work is the description of the anatomy of the perineum and the structures of the female pelvis. The book is lavishly illustrated; but while the color photographs are all that can be desired as works of art, less pretentious but larger plates or diagrams would be of more service to the reader. The volume is sure to be useful to every one who practises obstetrics, and will prove a valuable addition to the textbooks on that subject.

CASE HISTORIES IN DISEASES OF WOMEN, including Abnormalities of Pregnancy, Labor, and Puerperium. A clinical study of pathological conditions characteristic of the five periods of woman's life, by CHARLES M. GREEN, A.B., M.D., Professor of Obstetrics and Gynecology in Harvard University, Senior Surgeon for Diseases of Women, Boston City Hospital, Visiting Physician Boston Lying-in Hospital. With 11 full-page plates, one cut, and 25 charts in the text. Price, \$4. Boston: W. M. Leonard, 1915.

The author divides his book into five sections, dealing with the five epochs of woman's life, namely. Infancy and Childhood, Puberty and Adolescence, Maturity, the Climacteric, and Senility. Each section has a short introduction, followed by a brief discussion of the functional disorders, malformations, infections, traumata, and neoplasms incident to its particular epoch. Then follows in each section the presentation of illustrative cases. It is this feature that gives the book its distinctive character. Each case is discussed under the following headings: history; diagnosis; treatment and result; comment. The comments are very valuable, as in them the author thoroughly analyzes the diagnosis, treatment, and result, frequently making valuable comparisons between the case under discussion and similar cases that may require different handling. The book has the stamp of authority and presents in a thorough and interesting way the whole subject of gynecology.

ANATOMY OF THE BRAIN AND SPINAL CORD WITH SPECIAL REFERENCE TO MECHANISM AND FUNCTION, FOR STUDENTS AND PRACTITIONERS. By HARRIS E. SANTEE, A.M., M.D., Ph.D. Professor of Nervous Anatomy in the Chicago College of Medicine and Surgery, Medical Department of Valparaiso University; Professor of Anatomy in Jenner Medical College, Chicago; Member of Association of American Anatomists, etc., etc. Fifth Edition, Revised and Enlarged with 158 Illustrations, 46 of which are Printed in Colors. Price, \$4. Philadelphia: P. Blakiston's Sons & Co., 1915.

THE fourth edition of this work appeared in 1907, and considerable new matter has been incorporated without involving much increase in the size of the volume. A chapter is added on the embryology of the cerebrospinal axis. Aside from this the original arrangement has practically not been disturbed, this even including the paragraphs, the innovations appearing chiefly in the text of the latter, and in the form of citations from recent authors. Nearly one half of the illustrations are original, and new ones are to be found throughout the book, which may, perhaps be referred to as almost a classic.

WISHFULFILLMENT AND SYMBOLISM IN FAIRY TALES. By Dr. FRANZ RICKLIN of Zurich. Authorized Translation by Dr. WM. A. WHITE of Washington, D. C. Price, \$1. New York: The Nervous and Mental Disease Publishing Company, 1915.

THIS number of the Nervous and Mental Disease Monograph Series presents an exceedingly interesting discussion of the psychology of fairy tales. The importance of the part played by wishfulfillment is easily recognized in the heroes and beautiful ladies and bags of gold, to say nothing of supernatural accomplishments like the seven-league boots and the hat that made its wearer invisible. The matter of symbolism is not so clear. One can of course see the wealth of symbolic expression found in all folk and fairy tales, and the author has demonstrated how cleverly these symbols can be translated. Sex instinct is, of course, made to play a great part and no doubt rightly so since it must have been even more dominant in the days that the fairy tales were made than at the present time. Dr. White's translation is admirable in its preservation of the spirit of the original and in its easy style.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 6, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

The Importance of Syphilis Often Unsuspected in the Production of a number of Apparently Unrelated Disorders.—Dr. LEWELLYS F. BARKER of Johns Hopkins University presented this paper which was read by Dr. Sidney R. Miller of Baltimore in which he summed up twelve discoveries in the last ten years which had led to the speedy improvement in diagnostic methods and an increase in the efficacy of therapeutic measures in the treatment of syphilis. He declared that it might justly be said that in the knowledge of no other disease had so many advances been made in the last decade. On reading the accounts of cases studied before the newer diagnostic methods were available, one felt how sadly at a loss the older clinicians were in arriving at a certain diagnosis; they had to be contented largely with "conviction" and "belief" rather than with objective data which was decisive in the differential diagnosis, even though now a probability diagnosis was the only one possible, especially when there was a question of the simultaneous existence of a constitutional lues and of some disease of an organ that might or might not be due to lues. But to a very large extent, the mere "belief" of former days could now be replaced by "certainty." Dr. Barker epitomized the histories of seven cases of syphilis where the existence of the disease was denied and the patients presented symptoms respectively of bronchiectasis following pneumonia; sacculated aneurysm; general arteriosclerosis; indolent swelling of the tonsil; epilepsy; sudden loss of vision in one eye; diabetes mellitus with aphasia and general atherosclerosis. The Wassermann was positive in every case and the patients improved under antiluetic therapy. He gave a list of nineteen conditions in which it was especially important not to overlook the possibility of an existing lues. They were as follows: (1) Long-continued fever otherwise unexplained. (2) Obscure nervous cases, both functional and organic. (3) Chronic laryngitis, tracheal and bronchial stenosis, bronchiectasis and unexplained infiltrations of, or masses, in the lungs or pleuræ. (4) Aneurysms. (5) Aortic insufficiency, especially when unaccompanied by other valvular lesions. (6) Heart-block and other cardiac arrhythmias. (7) Arterial and venous thrombosis. (8) Certain grave anemias. (9) Paroxysmal hemoglobinurias. (10) Indolent nodules in the tongue and tonsils. (11) Enlargements of the liver and of the spleen. (12) Strictures of the rectum. (13) Atypical joint diseases, and especially obscure diseases of the spine. (14) Thickening of, or nodules in, the bones, especially when accompanied by nocturnal pain. (15) Unusual forms of renal disease. (16) Chronic orchitis, or nodules in the testes. (17) Repeated miscarriages without apparent cause. (18) Stillborn children. (19) In disorders of metabolism and of internal secretion, especially in bizarre cases. Dr. Barker then gave the histories of two cases in which it was possible to rule out syphilis though the patient himself feared that he had it. In the first case the roentgenological reports favored aneurysm; the Wassermann was negative but he improved under radium treatment. The second case gave a history of ulcer motte two years before which had been followed by salvarsan treatment. He was suffering from syphilophobia and feared also impotency and insanity. The Wassermann was negative and the patient gained weight and there was marked amelioration of the symptoms under a treatment of reassurance and a thorough rest-cure with cacodylate of soda injections. Such an instance as this showed how helpful it was to be able definitely to say to a patient or to his family physician that no luetic infection was present. Among the many conditions often believed to be luetic in origin, and in which sometimes it had to be admitted that a luetic factor was present, but which often occurred in the entire absence of lues were the following: (1) Cerebral apoplexy. (2) High blood pressure cases. (3) Contracted kidneys. (4) Multiple sclerosis. (5) Certain suspicious lesions, especially those due to sporotrichosis, or blastomycosis of the bones, lungs, or subcutaneous tissue. (6) Psychoneurotic states accompanied by syphilophobia. (7) Graves' disease. The more his experience grew, the more was he inclined to take as a

diagnostic aphorism "When in doubt have a Wassermann test made; when not in doubt, still have a Wassermann test made."

Syphilis in General Surgery.—Dr. EDWARD MARTIN of the University of Pennsylvania presented this communication. He said that to the surgeon syphilis was of import because of its prevalence; its protein clinical manifestations, closely simulating tumors, or the proliferation, or destructive effects of other infections; but more particularly because, unlike all other infections, its direct lesions were so consistently, effectually, and promptly bettered or cured by medication that, with some exceptions, operative measures constituted a species of malpractice. Hence, to the surgeon, the questions of incidence and diagnosis were major ones. As to the incidence of syphilis; a clinical examination of the West Point cadet corps failed to show a single case of syphilis, but the Wassermann survey indicated a five per cent. incidence, from which it seemed clear that from two to five per cent. of the commissioned personnel of the army were syphilitic at the time they entered the service. Since applicants to West Point were physically picked men, the prevalence of syphilis among college men in general was probably slightly greater than it was among West Pointers. (Vedder's "The Prevalence of Syphilis in the Army.") From a Wassermann survey of candidates for enlistment, he concluded that about 20 per cent. of the young adult male population from which the army was recruited were affected with syphilis. Out of 100 cases taken at random from the medical wards of the University of Pennsylvania hospital, there was a positive Wassermann reaction in 19 and of these only two gave clinical evidence of syphilis. These cases entered the hospital for the cure of diseases ranging from cholecystitis, renal sclerosis, gastric ulcer and tuberculous pyelonephritis to goiter and most of them exhibited neither characteristic history nor clinical signs of specific disease. Concerning diagnosis, the surgeon asked two questions: 1. Was the lesion under consideration syphilitic? 2. If not, had an underlying syphilis a distinct influence on its progression, or upon the outcome of surgical intervention undertaken for its cure? If these two questions could be answered in the negative, the query as to whether the patient had or had not syphilis was of minor immediate moment, though it was true that the spirochetæ, exhibiting a special predilection for the perivascular tissues and the heart muscle, by the devitalizing effect consequent on impaired nutrition predisposed to all other infections, to neoplasms and to slow ulcerative processes. Regarding the first question "Was the lesion syphilitic," with one exception, the extragenital chancre, surgical intervention was rarely proposed for the relief of either primary or secondary syphilis. But not infrequently, chancre, occupying other than its usual habitat, was regarded as epitheliomatous and excision was ordered, particularly in the case of digital chancre as it affected medical men; it was painful, persistent and atypical in appearance and not until it had been cut, curetted, cauterized, and otherwise stimulated to wider growth, and usually not until the axillary nodes had been excised by a sympathetic colleague, did the patient come to "the man higher up," by which time, even though spirochetæ were not recovered from the ulcerating surface, a positive Wassermann and often a secondary eruption established the diagnosis which should have been made by the microscope weeks before. The rapid evolution of chancre of the lip with the prompt and characteristic lymphadenitis were sufficient to exclude cancer. Nevertheless, some of these cases were operated upon; but the cutting of a wedge, quite inadequate for cancer, did no particular harm in syphilis, though there was resultant deformity. The major difficulty experienced by the surgeon was in the distinction between gumma and malignant tumor, a difficulty greater than ever before, since the profession was waking to the need of early intervention, and differential diagnosis of tumor cases in the early stage of development, either from rate of development or physical characterization, was impossible. Concerning bone swellings, the x-ray gave, even at the early stage, such pictures as usually enabled the determination with a fair degree of certainty, the syphilitic, tubercular, or neoplastic nature of the enlargement. But no such help was afforded in tumor of the soft parts; and in the absence of a history, or associated signs, the method of choice was microscopical examination, or wide excision, when it involved neither crippling nor gross deformity; or laboratory tests and the effect of vigorous antisiphilitic treatment. If

within a week, or at most two weeks, antisyphilitic treatment did not cause improvement, regardless of a positive or negative Wassermann, the lesion should be considered non-syphilitic and so treated. The betterment of a specific lesion under well directed treatment occurred quickly. There were in hospitals at this moment thousands of patients perishing from the corrupting influence of a positive Wassermann upon the mind of the surgeon; drained by the steady progression of a condition which called for prompt surgical relief, and even more actively sapped by the long-continued and futile administration of mercury, arsenic and iodide of potassium. When the lesion was surely non-syphilitic, though the Wassermann was positive, the question arose as to supplementing the surgical procedure by specific treatment; nor, if it be accepted that a positive Wassermann was a proof of active spirochetæ and that a harmless course of treatment would either quiet or kill them, would any but an affirmative answer seem logical. The reason for not so answering and acting was based on the absence of gross functional or structural changes.

Syphilis in Neurology.—Dr. JOSEPH COLLINS discussed the subject from the standpoint of the neurologist. He stated that it was universally believed that certain diseases of the nervous system, with definite, unvarying lesions, had their sole origin in syphilis; these were tabes, general paresis, and most instances of cerebral and spinal endarteritis. They caused subjective and objective symptoms that were so constant and unvarying as to be considered characteristic or pathognomonic. When all the diagnostic means at their disposal were employed, they offered little or no difficulty of early recognition and all hope of their successful treatment rested upon their early detection. If the so-called positive reaction was found in the serum and cerebrospinal fluid, if the globulin of the fluid was increased, if it reduced Fehling's solution, and if the number of cells was increased beyond 4 c.c., then the diagnosis of syphilitic disease of the central nervous system or its constituents was assured. There were, however, many other diseases of the nervous system whose origin was in syphilis which were not attended by pathognomonic subjective or objective symptoms, and they were far more numerous than the rank and file of the profession suspected. They paralleled in their clinical display nearly every organic disease of the central nervous system and many of the functional ones. Dr. Collins said that, excluding cases of tabes, general paresis, and cerebral endarteritis, he had tabulated 245 cases that were diagnosed syphilis of the nervous system and distributed them under the various diseases to which they conformed clinically. This list justified the statement that syphilis was of great importance in the production of a number of apparently unrelated disorders, and that syphilis of the nervous system might display itself in the guise of nearly every functional and organic disease of the nervous system that pursued a subacute or chronic course. This statement was not so appalling as it might appear at first sight, since the syphilitic diseases that caused these clinical syndromes were all susceptible to amelioration, and if treatment was applied early, vigorously, and appropriately, to cure, in many instances. Moreover, when these diseases were due to other causes than syphilis, many of them were in no wise amenable to treatment. This was the chief incentive to the detection of their origin. The recognition then of the true dependency of these diverse conditions upon syphilis became an important matter. One should suspect syphilis as the cause of disease of the nervous system in every instance in which the cause was not obvious. One should be more than suspicious of its existence in individuals who were sterile or barren, or who aborted without attribution. One must make the diagnosis conclusively of syphilis of the nervous system in every instance in which a positive reaction was found on more than one occasion and by different observers, in the blood serum and cerebrospinal fluid. The serological examination constituted the most important evidence that was available in the procedure of diagnosing these atypical cases of syphilis of the nervous system. Dr. Collins said the staff of the First Division of the Neurological Institute did not make a diagnosis of syphilis of the nervous system from the laboratory reports, but in every case of nervous disease in which the cause was not obvious they made the complement fixation test upon the serum and cerebrospinal fluid, and the latter

was examined for globulin and pleocytosis. When the laboratory report was inconclusive or paradoxical the fluids were submitted to two other laboratories, and the results compared and a decision made according to the preponderance of the evidence. In the face of negative laboratory report on the serum and cerebrospinal fluid a positive diagnosis of syphilis was not made in the class of cases under consideration unless at least one of the pathognomonic symptoms existed. Of these the most important was the pupil of irregular outline, which did not respond to light. The pathognomonic symptoms were never early symptoms, and if one waited for their appearance before naming a diagnosis their disease would have reached a stage when it would no longer be amenable to treatment. In this class of cases the symptoms were frequently not even suggestive of syphilis of the nervous system, but there was something about their character in tenacity, association, and conduct that suggested to the experienced physician their true origin, but it was difficult to give specificity to such symptoms or features for there was nothing that was characteristic. In a general way it might be said that the occurrence of headache, fugitive or persistent pain in the neck, the extremities, the trunk, stiffness, paresthesia, disorder of urination, transient ocular palsy, mental depression without obvious attribution, or discoverable cause, should suggest syphilis. Yet it would be absurd to say that any or all of these symptoms were so suggestive of syphilis of the nervous system that the diagnosis should be made. The Wassermann test was not made as a routine measure in the Out Patient Department of the Neurological Institute, but in the nine months that elapsed from April 1 to December 31, 1915, syphilis must have been suspected in 465 cases and the reaction was found to be positive in 150 of them. In several cases in which their suspicions were not substantiated, further investigation of the serum and of the cerebrospinal fluid revealed syphilitic disease. If the cases of "root neuritis" were included under meningitis, where undoubtedly a great many of them belonged, a third of their cases were to be found in this category, and it might safely be asserted that upwards of one-third of all cases of syphilis of the nervous system were founded anatomically in meningitis. The enormous importance of serological studies in all cases in which there was any suspicion of involvement of the meninges should be emphasized. Dr. Collins cited cases which brought out points in reference to the diagnosis and the difficulties in determining the diagnosis in pseudo-paresis and general paresis, disseminated cerebrospinal syphilis and insular sclerosis, syphilitic myelitis, syphilitic muscular atrophy, cerebrospinal meningitis in the guise of syringomyelia, syphilitic root neuritis (a dependency of meningitis), acroparesthesia, which was a root symptom in the majority of cases, neurasthenia redivivus, insomnia, epilepsy, neuritis and polyneuritis, shivering attacks and choreic movements, and rheumatism in which syphilis of the nervous system was the underlying pathological condition. Multiplicity of symptoms had been regarded as a striking feature of syphilitic disorders, but the allegation was not founded in fact. Many of the patients who had furnished the foundation for this contribution had one or two symptoms only, or at least that was all they related. The character of the symptoms often varied in such a way as to indicate that different tissues were involved at different times. Again syphilis often involved simultaneously several components of the nervous system and different levels. The symptoms might indicate that the entire cerebrospinal axis was involved. The best designation that could be given these cases was cerebrospinal meningitis, predominantly vascular, or parenchymatous. In the treatment of syphilis of the nervous system one must take cognizance of both the disease and the individual; for the former, salvarsan and mercury; for the latter, consideration and encouragement.

Dr. BERNARD SACHS said that the point of view regarding syphilis as an etiological factor in nervous diseases was of tremendous importance. He had been most impressed with the large number of cases of grave syphilis that existed. Therefore he thought it well that he should devote a few minutes to the consideration of this especial subject. It was astonishing to find how often during the past few months at the Mount Sinai Hospital, they met with these cases of grave syphilis. There were cases of cortical encephalitis which yielded promptly to treatment, but perhaps the gravest of all

forms of syphilis which were met with, a surprisingly large number, were the instances of basilar syphilis, cases in which the symptoms began with involvement of the cranial nerves, particularly the cranial nerves which had their origin in the pons or medulla. These cases began, as a rule, with general malaise, followed by rigidity, headache, intracranial pressure, and marked respiratory and bulbar symptoms. In one case artificial respiration was maintained for hours to prevent a fatal issue, and after normal respiration had ceased. The cases of basilar syphilis were not as frequent as compared with the other forms, but they were quite characteristic. He believed that the next gravest group of cases were those of cortical encephalitis, but many of these yielded to treatment. With regard to other forms of grave syphilis of the nervous system he thought it worth while to mention the large group of epilepsies. The number of idiopathic epilepsies was growing smaller and smaller. The cases appeared suddenly in adult life without renal or cardiac diseases. Some of these were unquestionably of syphilitic origin. Dr. Sachs took issue with what had been said with regard to the diseases supposedly due to syphilis; this disease could be associated with every form of central nervous disease. In his experience and service at the hospital and in private practice the Wassermann reaction was of extreme importance as a diagnostic aid. But there was a certain number of Wassermann-fast cases in which the treatment could not change the blood reaction. Regarding the inclusion of the typhoid spine, he said that gave him an opportunity of speaking of a group of cases of syphilitic spondylitis; he had met with many cases of spondylitis syphilitica, in which the tuberculous and traumatic element could be excluded, where the examination of the blood and spinal fluid led to the diagnosis. The greatest of all surprises in regard to the syphilitic origin of the disease occurred in trigeminal neuralgias. There were many cases that would not yield to any form of treatment, even after the teeth had been extracted, deviations corrected, etc., but after the administration of salvarsan and mercurials the neuralgia disappeared promptly. Dr. Sachs said he wished to paraphrase the remarks of Dr. Barker:—"If in slight doubt have a Wassermann; if in grave doubt have it done by two or three observers."

Dr. BOLESŁAW ŁAPOWSKI said that the papers presented, according to the program, were to bring to their consideration pathological conditions which, although due to syphilis, not only had been treated as such, but their connection with syphilis had not been even suspected. Only the advanced methods of the diagnosis of syphilis taught the physician to recognize the true etiology of the disease and thus its proper treatment. Considering the papers of the evening, and especially the paper dealing with diseases of the nervous system, from that standpoint of view, he wondered what the syphilographers, who were no more with them, Robert W. Taylor, Prince A. Morrow and others, for instance, would have said could they have come back to earth for a few hours to-night and listened to the last reader's discussion of 250 victims of about 30 diseases of the nervous system due to unsuspected syphilis which were discovered only by the new methods of examination of the patient. They would ask why did the reader of the paper not suspect syphilis and look for it in those patients? He said they would refer them to the old classical books on syphilis, from which it could be learned that in many of the mentioned diseases the prime factor was syphilis, and in nearly all of them, even including trigeminal neuralgia, discussed by Dr. Sachs, syphilis was to be suspected and searched for. By a thorough and critical examination of the clinical symptoms obtained not from a standpoint of the neurologist alone, but from the examination of the skin, the eyes, visible mucous membranes, bones and the internal organs, a corroborative evidence of past or present syphilis could be found. And in cases where clinical or laboratory examinations failed to show the presence of the suspected syphilis, the classical method of "exjuvantibus" even at present still remained the ultimate unfailing refuge of the physician. There was an advance in medicine, especially in their knowledge of syphilis which helped them to detect this disease in unsuspected cases, but it had not, in his opinion, been presented to them in the symposium of to-night.

Dr. HUGH B. BLACKWELL called attention to syphilis as it affected the auditory nerve; in the advanced cases of deafness it was almost impossible to help these patients; but if recognized early and active treatment

was instituted this grave condition might be prevented. This condition affecting the auditory nerve was one of the most tragic of all their diseases. If the general practitioner was more on the lookout for such cases and treated them actively these serious symptoms would be prevented.

Dr. LEON T. LE WALD said that out of a series of 2,000 cases referred to them for examination, syphilis of the stomach was shown in 11 instances. Some of these cases had been submitted to operation; sections had been taken but no microscopical examination made. What was removed was considered to be either an ulceration or a new growth.

Dr. MAX EINHORN spoke of syphilis of the liver where the symptoms simulated cancer. Under anti-syphilitic treatment these patients did well.

Dr. JEROME M. LYNCH said that he thought it was important that the surgeon should be on his guard and eliminate syphilis, for, whereas the physician could not do any harm, the surgeon could aggravate the condition by his activity. He referred to a few cases under the branch of surgery in which he was interested, that was, diseases of the intestines and rectum. A man suffering from hemorrhoids for a number of years had been treated at various clinics and operation had been finally suggested, which the patient had postponed owing to the demands of his occupation. On examination, Dr. Lynch was struck by the relaxed condition of the sphincteric muscle. It was characteristic of syphilis of the spinal cord to find this muscle absolutely contracted and on examination of such a patient to find it flabby and relaxed. The patient denied syphilis, but admitted being exposed to it on several occasions. A Wassermann was made and it was four plus; the man was referred to Dr. Fordyce and appropriate anti-syphilitic treatment instituted, under which the patient improved. If there had been an operation the condition would have been very much aggravated. Dr. Lynch cited other cases; one of severe abdominal pain; another, a doctor from Australia, in which the gall-bladder had been drained, and the appendix removed; on examination it was found that the patient had tabes; he was referred for antisymphilitic treatment and his condition improved.

Stated Meeting, Held January 20, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

The Serum Diagnosis of Syphilis.—Dr. HOMER F. SWIFT said that although the application of the Wassermann reaction had become one of the most common diagnostic procedures, one still occasionally heard objections as to its value. It had been thought that the reaction was due to a true antigen antibody (complex combination) but the discovery that lipid substances also gave fixation with syphilitic sera showed that there was a new, or rather heretofore unrecognized, mechanism in immunity. This with the fact that certain other diseases also gave positive reactions with so-called Wassermann antigens, caused the confusion and doubt which had arisen. The true nature of the reaction was not understood, nor could it be satisfactorily explained in terms which were used in other immune reactions. In performing the test, five different biological substances were employed, four of which might be considered as the reagents which had not the fixed value of chemical bodies, but varied in their properties according to the method of preparation, age, manner of preserving, and other factors which were not understood. The problem was to grade the strength of the various components so that the highest percentage of specific reactions might be obtained and at the same time the minimum number of non-specific reactions. Because of the lack of uniformity in performing the test the results should be judged from the clinical viewpoint. The most satisfactory reactions were performed in a laboratory which was in close touch with the clinical material from which emanated most of the sera tested; in such a laboratory the controls were not alone the sera which were introduced especially for the purpose but many others tested each day. If the reports from a laboratory varied to any marked degree when the sera from a group of patients was submitted from time to time it was safe to conclude that the methods employed in that laboratory were not well standardized. Keeping in mind that it was possible to grade the intensity of the reaction, as either too sensitive or too weak, it was well to know that

whatever level was chosen could be fairly closely maintained by paying attention to the following points: (1) A certain standard for the various components of the hemolytic system, which must be tested each day; (2) the use of several antigens and the comparison of a new one with old ones of known value before accepting it; (3) the insertion as controls not only of sera which had on the previous day given strong positive and completely negative reactions, but also of a serum which had given partial fixation. This was the most important control, for by means of it one was always able to determine whether his reactions were of approximately the same intensity from day to day. This uniform level of the reaction was especially required when the serum of a patient was to be tested after the provocative injection of salvarsan. In regard to types of antigens, practically the only variation from the techniques which had stood the test of time had been the substitution of various forms of lipoids for the extracts of syphilitic livers originally used as antigens. The antigen with the most constant value was the cholesterolin reinforced alcoholic extract of human or guinea-pig hearts, which also gave the highest percentage of positive reactions in all stages of syphilis, but especially the late forms; it also persisted longer in the serum of a patient under treatment. The chief criticism brought against it was that it gave too high a percentage of positive reactions in non-syphilitic patients, but with proper precautions the occurrence of non-specific reactions was rare. One occasionally encountered a serum which gave a positive reaction with one method or antigen and negative with the others, and repeated tests with serum obtained at different times from the same patient showed the difference to be constant. This paradoxical reaction emphasized the necessity of testing each serum with at least two, and better, three or more different antigens. It was well recognized that the Wassermann reaction was not a specific reaction for syphilis, but one highly characteristic of the disease and that positive reactions were found in a fairly high proportion of some other diseases, but it was safe to call the reaction non-specific only if the percentage of positive reactions exceeded the percentage found in all people. In the Wassermann there were group reactions as well as in the other diseases caused by spirochetes, namely, yaws and relapsing fever, also trypanosomiasis and malaria which reacted positively and were amenable to salvarsan therapy. It was well established that during the period in which numbers of the malarial parasites were in the circulating blood a positive Wassermann could be obtained, but this disappeared rapidly under genuine therapy. In tuberculosis, malignant disease, and diabetes, the reaction had been reported positive, but this might often be explained by the presence of a concomitant syphilis. In certain of the acute infections, such as scarlet fever, pneumonia, and poliomyelitis, a transient positive reaction was occasionally encountered, but it disappeared with or shortly after the crisis; a positive reaction in the cerebrospinal fluid of these patients was never encountered. Occasionally the blood of uremic patients reacted positively, which did not necessarily mean they were due to the uremic state for syphilis was doubtless a contributing etiological factor in many cases of Bright's disease. The demonstration of the *Treponema pallidum* in a suspicious ulcer proved the lesion to be syphilitic; the demonstration of a positive Wassermann reaction proved that generalized distribution of the virus had taken place, and the earlier diagnosis was made and treatment instituted, the better was the chance of complete eradication of the disease. When an untreated individual in the primary stage showed a positive Wassermann reaction, he was the subject of generalized syphilis. The appearance of a positive reaction usually occurred in the third week after exposure, and as that was the most favorable period for treatment, it was very important to realize the comparative value of the Wassermann reaction and spirochete search. It had been found that combined treatment with salvarsan and intramuscular injections of mercury affected the reaction more rapidly and permanently than did the administration of either alone. The reaction disappeared more rapidly in the early stages of the disease than in the late ones, but disappearing reactions in late syphilis were better indicators of sufficiency of treatment than in the early stages. Little attention should be given to negative reactions in the first year of the disease and treatment should be continued for ten or twelve months. A persistent positive reaction indicated the

presence of syphilis somewhere in the body and in the first three or four years treatment should be continued until the reactions remained negative. With reactions that could not be influenced a course of treatments should be given annually. In aortitis, persistent reactions while the patient was under mercury and salvarsan disappeared upon continued administration of iodides. In conclusion, Dr. Swift said the Wassermann reaction should be regarded as a biological response to the activity of the syphilitic virus in the body, a reaction not specific but highly characteristic of the disease, and it should be recognized that it might occur in certain other conditions which should be considered in cases of doubt. Because of the variability in the various reagents and the lack of uniformity in performing the test in various laboratories, it was essential that there be close cooperation between the laboratory and the clinician, for the clinician should be the interpreter of the reaction.

The Study of the Cerebrospinal Fluid, and Its Value to the Practitioner.—Dr. GEORGE DRAPER said that in order to discuss intelligently the cerebrospinal fluid in syphilis it was necessary to consider certain points which might sound almost like truisms, but which perhaps, therefore, should be seized upon and held the more firmly. In the first place syphilis was a general systemic infection by the *Spirochæta pallida*. The body's reaction to the invasion was unusual in the development of a partial immunity, so that the disease tended to become chronic with localizing areas of infection. Extremely acute reaction might occur. But the important point was that syphilis was not a disease of the skin, or of the heart, or of the bones, or of the central nervous system, any more than typhoid fever was a disease of the intestines, or rheumatic fever a disease of the joints. Syphilitic immunity was at present not understood, but it appeared that there was a very definite immunity developed during the long course of the malady, as witness the latent periods, the disappearing of the spirochetes from the blood, and the localization of the disease. Since the introduction of salvarsan and the appearance of the amazing phenomena of Herxheimer and nerve relapses it had been suggested that isolated foci of infection, which lay dormant under the influence of the immunity induced by active lesions elsewhere, showed increasing activity when the immunity stimulating spirochetæ of those other lesions were killed by salvarsan. These four generalizations indicated clearly that syphilis in the human was a biological problem, one so complex that it must be attacked by every effort of clinical observation and the more accurate biological methods. One of the latter methods was the lumbar puncture and the study of the spinal fluid. The time had come when hesitation to use this procedure should cease. The technique was simple and safe and practically painless. Under no circumstances, however, should the diagnostic puncture be made with the patient in any but the horizontal position in bed. Four examinations to which the fluid was subjected were a cell count, globulin determination, Wassermann reaction, and Lange gold test. Any changes from the normal must be looked upon with suspicion, no matter whether the serum Wassermann was negative and the patient honestly denied any knowledge of the infection. Such changes were (1) definite increase of pressure; (2) multiplication of cells; (3) positive globulin, no matter how faint, and (4) positive Wassermann reactions in amounts of 1 c.c. or less. It was clear that a lumbar puncture was an absolutely necessary part in the diagnosis and treatment of the early days and weeks of the disease. In conclusion Dr. Draper summarized as follows: (1) The cerebrospinal fluid showed changes in 100 per cent. of the early cases. (2) The globulin test was the first to appear positive and the last to go. (3) There might be marked pathological changes in the fluid of cases of late syphilis for long periods of time before any signs or symptoms developed. (4) All cases of frank tabes, paresis, cerebrospinal syphilis, etc., had pathological fluids. (5) In a certain group of syphilitics with vagus nerve disturbances, the spinal fluid might be normal in all points except the globulin. In such instances the isolated globulin finding became highly suggestive of meningeal involvement of syphilitic nature. A provocative treatment should be instituted in these instances. (6) Under treatment pathological fluids could be brought to normal, but the globulin was the last pathological change to disappear. (7) Examination of the spinal fluid was absolutely essential to the proper care and study of general syphilitic infection.

The Value of the Colloidal Gold Test in the Diagnosis and Prognosis of Syphilis of the Central Nervous System—and the Value of the Microscopical Diagnosis by Dark Field Illumination. Illustrated by Lantern Slides.—Dr. JOHN A. FORDYCE said our conception of syphilis as a general infection had been a process of gradual evolution largely due to clinical observation. The methods of precision elaborated in this field of medicine had not only confirmed these observations but had added so much exact knowledge during the past ten years that it might well be said a notable epoch in our real conception of the disease had been made. He said it could not be emphasized too frequently or too emphatically that the fate of the syphilitic individual depended largely upon the early diagnosis of his infection and the intensity with which his treatment was carried out in the first six months. It was in the accomplishment of this purpose that the modern aids to diagnosis had rendered the practitioner invaluable service. The speaker cited cases to illustrate that it was impossible for even a trained observer to recognize by his sense of sight and touch alone all that could be revealed by the laboratory. Chancroids frequently harbored the organism of syphilis and owing to the longer incubation period of the latter did not develop their characteristic features until after the expiration of two or three weeks, or might entirely fail to develop any induration. The secretion of all these lesions should be searched for the *Treponema pallidum* and failing to find it a favorable prognosis should be withheld until repeated examinations, including the Wassermann reaction, had been made. Initial lesions were so protean in appearance that atypical chancres would frequently go unrecognized without this means of corroboration. The dark field was especially valuable in developing chancres before they acquired their clinical characteristics as their nature might be confirmed in a few minutes. The promptness with which treatment could be instituted in these cases and their favorable prognosis was obvious. The examination of the spinal fluid enabled them to determine the activity of the luetic process in the brain or cord, to distinguish the various pathological types affecting the central nervous system and in many cases to differentiate between these and non-luetic infections. The writer cited cases to show how the tabetic syndrome might be simulated by the multiple neuritis of diabetes or alcoholism and the real nature of the trouble only revealed by the spinal fluid analysis and the blood test. On the other hand patients with syphilitic involvement of the central nervous system and suffering from obscure pains, febrile attacks, irritability, gastric and rectal crises, memory failure, etc., were often treated for years for neurasthenia, rheumatism, neuritis, surgical affections, and various other conditions. In the light of more recent investigations an analysis of the spinal fluid was not complete unless the colloidal gold test was performed in addition to the Wassermann reaction and a cytological and chemical examination. The speaker gave a résumé of the theory of the reaction and its technique, and added that as a rule there was a parallelism between it and the other positive findings in the fluid. The typical paretic curve had been met with in every case of paresis examined and in three cases had been reversed by treatment to the luetic curve. This improvement, however, did not run parallel with the abatement of clinical symptoms, as one patient who in addition was negative in all the other laboratory findings was slowly deteriorating in spite of treatment pushed to the point of tolerance. Definitely syphilitic processes, as cerebral endarteritis, abortive or stationary forms of tabes, and some types of cerebrospinal syphilis, might give a completely negative Wassermann. It was in these cases that a supplementary gold test was of value in demonstrating the luetic nature of the conditions. Its greatest value, however, was in distinguishing between paresis and the conditions which simulated it as well as its prognostic significance in tabetics who showed no mental impairment but gave a paretic curve. Dr. Fordyce quoted a number of patients with tabes in whom the typical cerebral disorders as writing and speech defects, tremor and memory defects were absent, who gave with the gold chloride a complete discoloration in the first five to eight tubes. While these cases had not been observed long enough to warrant any definite pronouncement as to the prognostic significance of the paretic curve, post-mortem findings had taught that the anatomical changes in paresis may long antedate clinical manifestations. He felt that in patients who were under continuous observa-

tion, and especially those who were receiving intraspinal treatment where the fluid could be examined at regular intervals, the presence or the development of the paretic curve should excite a strong suspicion that later these patients might develop the clinical syndrome of paresis, and he was advising the family or business associates of such patients of the possibilities in the case. Active treatment in these cases might anticipate, delay, or arrest the degenerative cerebral changes. Lumière lantern slides were shown to demonstrate the complete precipitation of the gold solution in the first four to eight tubes in paresis, the so-called paretic zone, as well as the color changes in other types of syphilis of the central nervous system.

Dr. SYDNEY R. MILLER of Baltimore said that the ground had been very thoroughly covered in the papers of the evening, but at Dr. James' suggestion it might be interesting briefly to state the point of view at present held in the clinic of the Johns Hopkins Hospital. The opportunity seemed especially fortunate by reason of the fact that within the past week a paper had been read before the Johns Hopkins Medical Society by a physician from New York, in which the views presented were diametrically opposed to those outlined this evening. They were to the effect that inasmuch as the Wassermann reaction was a non-specific one, since it was often absent in cases known clinically to be luetic and by reason of the fact that their conception of the treatment of syphilis had really been very little modified since the introduction of the test, and since the same serum examined by five different observers frequently yielded widely divergent results, therefore the reaction was dangerous, of little clinical value, and probably had better be left alone. There could be no argument concerning the non-specificity of the reaction in the Ehrlich sense of the term. There was little danger of their seeing cases of yaws, recurrent fever, and frambesia in this part of the world. It was interesting, however, as was pointed out by Dr. Swift, that these diseases were etiologically and biologically closely related, and it might therefore reasonably have been predicted that a positive Wassermann reaction in these conditions would not be infrequent. Practically the only other disease which had ever given them questionable results had been malaria, but this condition was practically always easily ruled out by finding the malarial parasites and in the failure of this, a course of quinine, followed by a second Wassermann would usually decide a doubtful case. As a result of the experience of five different laboratories, they had come to feel that an unequivocal positive Wassermann reaction, preferably with three, but not less than with two, antigens, in a technique suitably controlled in which accuracy of result had not been sacrificed to delicacy of method, was clinically a specific evidence of existing syphilis. Where the Wassermann was positive and the clinical evidence had not been such as to lead one to expect this result, a rigid investigation was instituted with the result that one side or the other was shown to be incorrect in its conclusions. They felt that their experience had been by no means unique in that the Wassermann reaction had cleared up most difficult cases and in a number of instances had clearly shown the casual or constant etiological relationship of syphilis to the diseases under consideration. The point which needed the greatest emphasis, however, was that the closest cooperation must exist between the laboratory worker and the clinicians in the ward. The attempt to divorce one from the other was bound to lead to dangerous misinterpretations. This, however, was no more true of the Wassermann reaction than of all other laboratory methods with their recognized sources of error. There was nothing particularly remarkable about the fact that cases known to have clinical lues, from time to time gave negative Wassermann reactions, even in the absence of anti-luetic therapy. There were so many analogies familiar to one who had followed the general subject of immunology that it was scarcely necessary to go into them at this point. With reference to the statement that the Wassermann reaction gave discordant results in the hands of different observers though using the same antigens in testing the same sera, it should be pointed out that in the endeavor to simplify the technique of the original test and devise time-saving methods, that numerous modifications had been made, a number of which were lacking in the essential details described by Wassermann. This could scarcely be interpreted as an error inherent in the method, but undoubtedly was a strong argument

in favor of its universal standardization. The fallacy of the statement that their treatment of syphilis had not been advanced since the introduction of the Wassermann reaction, would become apparent to anyone who calmly analyzed the statement. It might be true that to a certain degree their ideas had not been materially changed; the point to be remembered, however, was that since the Wassermann reaction came into existence, more known luetics had been intelligently and persistently treated than ever before, particularly after they had passed into the symptomless stage of their disease. Moreover, more unsuspected conditions due to syphilis had been discovered and treated than was ever possible prior to the laboratory method of diagnosis. No doubt cases had been treated which were not suffering from syphilis, but rather from the faulty application or interpretation of a Wassermann test. The harm done by such misplaced therapy was nothing as compared with the good that had been achieved on the great mass of unfortunate sufferers. Just a word might be said here of the paradoxical reactions referred to by Dr. Swift. Out of a series of approximately 1,500 Wassermann reaction tests in which each serum or spinal fluid was tested against three different antigens, the results were parallel absolutely in over 97 per cent. of the cases. In seven instances fixation was given alone by the cholesterinized human heart antigen. In all of these a subsequent lumbar puncture revealed the fact that the individual was suffering from some type of central nervous system syphilis. This brought up two points which needed particular emphasis: 1. That a suspected spinal fluid should not be regarded as negative unless it was so when ten times the original volume suggested by Wassermann was used in the reaction. 2. The fact that physicians should demand a report which clearly stated against how many antigens and in what amounts a spinal fluid or serum had been tested. The cases referred to by Dr. Draper in which weak globulin reactions were the only evidence of some underlying abnormal condition, were extremely interesting and suggestive. Similar findings had been noted by them and in general they had found that positive globulin tests were most frequently the earliest signs of central nervous system syphilis and the last evidence of its existence to succumb to suitable treatment, the colloidal gold reaction excepted. In testing for increased globulin content, they had been impressed with the superiority of either the Ross-Jones or Pandy test, preferably the latter, by reason of the fact that but one drop of spinal fluid was necessary to give an immediate and decisive answer. This reaction described originally in 1910, deserved a much wider application. In their experience it had not proved over-sensitive.

Dr. E. L. KEYES, JR., said he agreed enthusiastically as to the status of the methods of precision in the diagnosis of syphilis as laid down in the paper of Dr. Swift. He could take no exception to any of his remarks or to the details of the technique as he had presented them. It was interesting to know that Dr. Miller in his conclusions did not agree with one of the other speakers. The Wassermann and other cerebrospinal fluid tests required no defense when properly and intelligently performed. What Dr. Miller said with reference to the necessity of a proper correlation of clinical and laboratory findings should be emphasized; there had been too much dependence on these tests in a perfectly stupid manner. For instance, he had recently seen a patient treated six months previously by salvarsan. Unfortunately his condition was not checked up by observations of the cerebrospinal fluid. The patient had drifted away after a short time having received insufficient treatment. One year afterward he had a relapse of his syphilis in the nervous system. The patient had this relapse not because the salvarsan had been given, but because it had not been followed up to sufficient lengths and guarded by a series of intramuscular injections to prevent an outbreak of syphilis in the patient whose resistance to the disease had been lowered by salvarsan. This same physician could not believe salvarsan was needed when the patient returned since the blood remained negative. He gave pills and the iodides. The lesions of the nervous system were little better for this treatment. There had been no examination of the cerebrospinal fluid. The laboratory findings had obscured the clinical indications in this instance. A little dabbling in laboratory findings leads the inexpert clinician astray, and it was to be hoped that if there were any such experts in this vicinity they were present this evening to hear Dr. Swift's paper.

Dr. EDWARD D. FISHER said that his discussion would

be from the clinician's standpoint, but that while he was speaking from the clinical side it should not be taken to mean that he was opposed to the laboratory. From his personal standpoint he would place the diagnosis of syphilis much more surely on clinical observations than on the laboratory findings. The clinical side had been studied for so many years that a pretty exact knowledge of the manifestations of syphilis of the nervous system had been established. He had been interested in the report that stated that the cerebrospinal fluid in apparently every case of primary syphilis gave findings showing a pathological condition. In this connection it might be mentioned that one might have syphilis of the heart, of the lungs, of the liver, of any organ, that syphilis, in other words, had a selective choice as to situation. Probably not more than 10 per cent. of the patients affected with syphilis had disease of the central nervous system. Again there was a selective choice of certain parts of the nervous system; in some cases there might be involvement of the meninges and blood vessels and in others of the cell structure. That had been observed clinically by Mott of London when he divided cases into meningovascular and cellular or parenchymatous, as tabes and general paresis. These conditions were entirely different; and they did not pass necessarily from one into the other, that was from the vascular to the cellular. Dr. Fisher said that in his experience with the early symptoms of syphilis one sometimes got a basilar meningitis and ocular paralysis and that under proper treatment these almost invariably cleared up. The laboratory might help one where he had cases of cerebral or cerebrospinal syphilis passing into general paresis; if that could be done they would have gone a great way in diagnosis. There were some clinical conditions in respect to which all seemed to be agreed and one of these was that paresis was rarely preceded by tabes, if the latter was typical in character.

Dr. SIGMUND POLLITZER said he shared the feelings of the previous speakers with reference to the necessity of correlation between laboratory and clinical work, and he had been in close touch with the laboratory for many years. As to the colloidal gold test, he was familiar with it though he had had no personal experience. It was of the greatest utility when it worked, but it was exceedingly difficult to carry out and on this account he doubted if it would ever be extensively employed. It was the duty of the practitioner when he saw a case of primary syphilis to make an examination for spirochetæ in the initial lesion. If he failed to do this he was guilty of the grossest neglect, because syphilis during the first few weeks or months was curable. He had not seen a case in the past five years which was properly treated during the first three months which was not cured. When one saw a case of syphilis in the early stage the diagnosis might be made by the dark field illumination, but this was not the only way. The India ink method, using the Grubler ink and taking pains to keep the ink free from contamination was absolutely reliable. As to the cerebrospinal fluid examinations, the majority of syphilitics showed during the first weeks some irritation of the central nervous system, but only a small proportion developed cerebrospinal syphilis and to treat these early cases for cerebrospinal syphilis by intraspinal injections was, in the present state of our knowledge, an unjustifiable procedure. Before dismissing a patient as cured the provocative salvarsan test should be employed and an examination of the cerebrospinal fluid made. Even when the Wassermann reaction was negative the cerebrospinal fluid should be examined. When the Wassermann test remained persistently positive in spite of all treatment, the cerebrospinal fluid should be examined. To come to the Wassermann test itself, Dr. Pollitzer mentioned that he had read the first paper on this subject from this rostrum nine years ago and soon after that had the Wassermann test made on his patients. He had had from four to five thousand Wassermann tests performed and so could speak authoritatively from the point of view of the correlation of clinical and laboratory findings. There was no single test that had the value of the Wassermann test, but it must be interpreted with a little intelligence. So far as the diagnosis of syphilis went, he felt that they would be lost without the Wassermann test. In many cases that were doubtful the Wassermann test gave definite information and subsequent treatment had demonstrated its correctness. Sometimes clinical observation and the Wassermann reaction were not in harmony and when this was the case the Wassermann test must be re-

peated, since there was always a possibility of some mistake in the laboratory. The Wassermann test was not an automatic process and it was perfectly possible for a mistake to occur. He had had several instances in which a case was reported strongly positive or negative in which he had expected the opposite result and he had sometimes proven the mistake in the laboratory on having the test repeated. A few years ago he had sent 30 specimens to four different laboratories, three of them connected with hospitals. The reports from the three laboratories on the same serum were in practical harmony, but those from the fourth, a private or unattached laboratory, did not agree. The warning deduced from this experience was obvious. It was the duty of the practitioner to employ the Wassermann test and have it made in a reliable laboratory; to make an examination for the spirochetæ on every suspicious ulcer, and in the later stages of syphilis before discharging the patient as well as in every case of a persistently positive Wassermann despite thorough treatment to have an examination of the cerebrospinal fluid.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

DISEASES OF THE SKIN. By HENRY H. HAZEN. Published by C. V. Mosby Company, St. Louis; 243 illustrations, including four color plates; 539 pages.

INJURIES OF THE NOSE, THROAT AND EARS. By ANDREW MAITLAND RAMSEY, J. DUNDAS GRANT, H. LAWSON WHALE, and CHARLES ERNEST WEST. Published by Oxford University Press, Warwick Square, E. C. London. 160 pages. Price, \$1.00.

INSTINCT AND INTELLIGENCE. By N. C. MACNAMARA. Published by Oxford University Press, London, England. 216 pages. Price, \$2.00.

DISEASES OF THE THROAT, NOSE, AND EAR. By WILLIAM H. KELSON. Published by Oxford University Press, London, England. Illustrated. 270 pages. Price, \$3.00.

EXTRA-PREMIER. By H. BRAUN, Dr. Phil. Published by Nationale Levensverzekering-Bank, Rotterdam. 130 pages.

A GUIDE TO GYNECOLOGY, IN GENERAL PRACTICE. By COMYNS BERKELEY and VICTOR BONNEY. Published by Oxford University Press, London, England. 452 pages. Price, \$6.50.

TRACHOMA, ITS PREVALENCE. By GORDON L. BERRY. Published by National Committee for the Prevention of Blindness, 130 East Twenty-second Street, New York. 40 pages. Price, \$40.00 per thousand.

DIE PATHOLOGIE UND THERAPIE DES ILEUS. By PROFESSOR W. KAUSCH. Published by Carl Marhold Verlagshandlung, Halle. 51 pages. Preis M. 1.40.

MODES OF RESEARCH IN GENETICS. By RAYMOND PEARL. The Macmillan Co., New York. 182 pages. \$1.35.

STATE HOSPITAL COMMISSION. Twenty-Sixth Annual Report. October 1, 1913, to September 30, 1914. Published by J. B. Lyon Company, Printers. 709 pages.

DISEASES OF THE STOMACH AND UPPER ALIMENTARY TRACT. By ANTHONY BASSLER. Published by F. A. Davis Company, Philadelphia. 881 pages.

THE ADOLESCENT PERIOD. By LOUIS STARR. Published by P. Blakiston's Son & Company, 1012 Walnut St., Philadelphia. 211 pages. Price, \$1.00 net.

FIRST AID IN EMERGENCIES. By ELDRIDGE L. ELIASON, M.D. Published by J. B. Lippincott Company, Philadelphia and London. 204 pages.

THE PRACTICAL MEDICINE SERIES. Vol. X. Nervous and Mental Diseases. Edited by HUGH T. PATRICK, and PETER BASSOE, M.D. Published by The Year Book Publishers, 327 S. La Salle Street, Chicago; 240 pages. Price, \$1.35. Price of the series of ten volumes, \$10.00.

THE PRACTICAL MEDICINE SERIES. Vol. IX. Skin and Venereal Diseases. Edited by OLIVER S. ORMSBY and JAMES HERBERT MITCHELL. Published by The Year Book Publishers, 327 S. La Salle St., Chicago; 240 pages. Price \$1.35. Price of the series of ten volumes, \$10.00.

BELLEVUE AND ALLIED HOSPITALS. City of New York. Thirteenth Annual Report. January 1, 1914 to December 31, 1914; 107 pages.

Therapeutic Hints.

Pediculicide.—Fluid extract stavesacre $\mathfrak{z}$ ii, dilute acetic acid, $\mathfrak{z}$ vi; for external use; apply three or four times a day until the nits have all been hatched.

Bronchopneumonia in Children.—The following non-depressing expectorant is recommended by Marfan:

$\mathfrak{R}$ Ergotin, gr. xv.
Strychnine sulphate, gr. $\frac{1}{12}$.
Mucilage, $\mathfrak{z}$ ij.
Distilled water, $\mathfrak{z}$ iv.

M. Dose for infants under six months of age, a teaspoonful twice a day; between six months and a year, three teaspoonfuls a day; from 1 to 2 years, four teaspoonfuls a day; and above 2 years, five teaspoonfuls a day. If there is any diarrhea the following mixture is to be preferred:

$\mathfrak{R}$ Solution of acetate of ammonia, $\mathfrak{z}$ ijj.
Tincture of cinnamon, $\mathfrak{m}$ xv.
Infusion of coffee, $\mathfrak{z}$ j.
Syrup of cinchona, $\mathfrak{z}$ ij.

M. Sig.: Four or five teaspoonfuls in the 24 hours.—*Medical Press and Circular.*

Use of Resorcin in Seborrhea.—W. K. Sibley says that for alopecia due to this condition resorcinol will generally be found most efficacious in a 2 per cent. solution. It is freely soluble in water, and should be rubbed into the whole scalp once a day. Even in a 2 per cent. solution, especially if it has been made some time, it will have a slight staining effect on fair or white hair. Care must always be taken that no alkaline preparations, such as alkaline soaps, are applied to the scalp, or a considerable dyeing of the hair will ensue; if therefore it is desirable to add an oil to the preparation used, some tincture of soap bark (tinct. quillaia) and not an ordinary soap should be used, such as:

$\mathfrak{R}$ Resorcin, gr. x.
Ol. ricini, m. xxx.
Tinct. quillaia, m. xv.
Aquam rosam, ad $\mathfrak{z}$ i.

—*The Practitioner.*

Iodine for Typhoid Carriers.—Kalberlah says that iodine in combination with charcoal will free the stools from typhoid bacilli very promptly. He gives from 8 to 15 minims of tincture of iodine in a glass of water from three to five times a day, wood charcoal in teaspoonful doses being given at the same intervals. In five cases in which this method was tried the bacilli promptly disappeared from the stools and did not return during a period of four months, examinations of the stools being made at five-day intervals. Discharge of bacilli in the urine may continue for a considerable period, but this can be speedily arrested by the administration of hexamethylenamine.—*Medizinische Klinik.*

Seborrheic Alopecia.—When the scalp is red and inflammatory, the following are useful applications:

$\mathfrak{R}$ Liq. carbonis deterg., m. xx.
Acid. hydrocyan. dil., m v.
Glycerini, m. x.
Aquam rosam, ad $\mathfrak{z}$ i.

or

$\mathfrak{R}$ Liq. plumbi subacet. fort., m. x.
Liq. carb. deterg., m xv.
Glycerini, m. xxx.
Aquam rosam, ad $\mathfrak{z}$ i.

PERSISTENT DEVELOPMENTAL ANOMALIES OF POSITION OF THE LARGE INTESTINE WITH ESPECIAL REFERENCE TO THE ASCENDING COLON AND CECUM.

By ROYALE H. FOWLER, M.D.,

BROOKLYN, NEW YORK.

ASSOCIATE SURGEON, GREENPOINT HOSPITAL.

INSTANCES of intraabdominal congenital malformations are not apparent as harelip and clubfoot and consequently have not been as frequently observed. The latter usually have come under the surgeon's care early in childhood, the former have been recorded in the course of post-mortem examinations, operations upon the living, and in cadaver dissections made for the purpose. With the increasing number of surgical operations and routine radiographic examinations of the chronic abdomen, these conditions will be found to be more common than statistics have heretofore indicated.

Some of these conditions directly or indirectly give rise to indefinite symptoms, others give rise to no symptoms, and it has occurred that, when the abdomen has been carefully explored in the course of an operation directed toward the relief of a neighboring diseased organ, certain of these anomalies have been brought to light.

In dealing with the large intestine, we note that there may be complete transposition, through failure to rotate during the developmental period. In case of incomplete rotation, the cecum may assume a position at any point between the right iliac fossa and the left side of the pelvis. It may be under the liver or to the left of the umbilicus. Because of malformations other than failure to rotate, as for example, congenital openings in the diaphragm, the colon may be contained in the sac of a hernia and situated in the pleural cavity. The writer has reported such a case.

Under title of "Non-descent of the Cecum and Absence of the Ascending Colon," congenital anomalies of the large bowel have not been frequently discussed in surgical literature. Thus Borden, in 1912, stated that in a careful search of the literature in the library of the Surgeon-General in Washington, he found the writers upon the subject included only Robinson, Treves, Fahrenholdt, Hartmann, Debert, and Lockwood.

Borden has, however, overlooked a few contributions pertaining to malposition of the cecum, notably those by Klose, Lardennois, Maxson, Morozoff, Smith, and Turschmid. Still other reports are revealed in a search under various titles, "Left Sided Appendicitis," "Failure of Colon to Rotate," etc. More recent contributions are by Vosburgh

and Delatour. Lejars, of Paris, has also contributed a valuable article upon "High Displacement of the Cecum and Appendix, Its Clinical and Operative Significance."

To cover the field completely, other contributions such as Transportation of the Viscera, and Anomalies in general should be consulted. Thus one paper by Armstrong relative to the subject is published under title of "Abnormal Position of the Duodenum," another by Malcolm, "Two Rare Anomalies Observed in the Course of Operation."

The writer desires to record the following cases:

CASE I.—R. R., male, age 32, station agent in employ of Long Island Railroad was seen in a consultation with Dr. N. S. Wadhams, July 31, 1912, at Westhamp-ton Beach, New York. He had been ill for two days.

FIG. 1.—Author's case. Complete non-descent of the cecum.

His chief complaints were peri-umbilical cramps and vomiting. The temperature was 101.4° F.; pulse 110, respiration 26. There were rigidity and tenderness in the right upper quadrant, somewhat low for gall-bladder infection and high for appendiceal. High appendicitis was diagnosed. The patient was removed at once to the Southampton Hospital and subjected to operation. After opening the abdomen a rather protracted search revealed the condition which is illustrated in Fig. 1. The appendix was adherent through its entire length to the posterior cecal wall. It is to be noted that the cecum in addition to preserving the embryonic position, showed the persistence of the conical type. The appendix was bulbous at the end, constricted at its middle. It was excised unruptured, the base tied off and the wound closed around a small drain, inserted into the bed which the appendix had occupied. Upon splitting the appendix it was found to be distended with pus. Following a superficial infection, the wound healed. When the patient was last seen in October, 1912, he was in vigorous, robust health carrying on his duties, perfectly cured, without bulging at the site of the incision, and with no symptoms

referable to the absence of the ascending colon and failure of cecum to descend.

Through the courtesy of Drs. Walter Sherwood, C. H. Goodrich and George I. Miller the writer is enabled to record cases which have come under their observation.

CASE II.—R. R., married woman, 31 years of age, was admitted to the Jewish Hospital Dec. 10, 1913, with the following history. The chief complaint was pain in the right hypochondrium. Present history: Onset five days before admission. Patient complained of cold, fever and sore throat. Two days later was seized with general cramp-like pain in the abdomen associated with chills and fever. No vomiting. The pain became localized in the right side of the abdomen but was more marked in the gall-bladder region. Bowels constipated for three days. Family history: Irrelevant. Past history: The patient is of regular habits; has good appetite, sleeps well. Constipated. No other previous illness. Last year had two attacks of cramp-like, sharp shooting pain in the right side of the abdomen. No vomiting, chills or fever. No icterus or pruritus. No clay colored stools. Menstruation began at 13 years of age, always regular, flow lasts four days, no pain. Married 13 years ago, has borne four children. The last child was born 17 months ago. Normal deliveries. No abortions or miscarriages. Patient is well developed and well nourished. Appears acutely ill. No icterus. Tongue coated. Head and neck, lungs and heart normal. Abdomen symmetrical. No masses or rigidity. Moderate resistance in right iliac fossa. Tenderness present over McBurney's point, but most marked over the gall-bladder region. No costovertebral tenderness. Liver: Dullness about 2 inches below ribs. Spleen and kidneys not palpable. Extremities negative. Temp. 104.6° F. Pulse 128, Resp. 32. Blood examination showed 20,000 leucocytes, 87 per cent. polynuclears, 13 per cent. lymphocytes. Urine Sp. Gr. 1034 acid, trace of albumin present. Sugar negative. Some hyaline, and granular casts, epithelial cells present.

Operation Dec. 10, 1913. Incision, four inches long through the outer border of the right rectus muscle. Peritoneum opened. Several loops of small intestine appeared in the wound. No ascending colon present. The cecum was distended and fixed by adhesions embracing the appendix which was situated beneath the liver. The appendix was adherent from base to apex and attached to the under surface of liver. The base of the appendix was first ligated and stump inverted. The appendix shelled out of its covering and the two edges of mesentery sutured with catgut. There was a well marked pericolic membrane over the cecum. No Lane kink. Uterus and adnexæ normal. Several adhesions which united the transverse colon and cecum to the gall-bladder were separated. The gall-bladder was normal. Sigmoid and descending colon were in the normal position. Abdomen closed. The patient made an uneventful recovery and left the hospital cured three weeks after operation.

CASE III.—Gertrude S., age 15, bookkeeper. Admitted Aug. 14, 1914, to the Methodist Episcopal Hospital, service of Dr. Walter Sherwood, complaining of pain in the right lower abdominal quadrant. One week previously (Aug. 7) the pain commenced suddenly in the epigastrium. There was no vomiting. Pain gradually shifted to right iliac fossa. It has remained continuous. Patient thinks she had no fever, bowels regular. Family and past history irrelevant. On examination, the patient was seen to be a well developed young girl who appeared acutely ill. Tongue coated, heart and lungs normal. Abdomen not distended, marked tenderness, slight rigidity in right lower quadrant. Liver and spleen not palpable. Extremities negative. On admission. Temp. 100° F., pulse 100, resp. 24. Urine negative.

Operation by Dr. Frank E. Brown. Right rectus incision. On opening the peritoneum, small intestines presented, no omentum. There were several adhesions on the right side which were broken up in an effort to locate the cecum and appendix. These structures were not found in the usual situation. Upon exploration of the left side about the level of the umbilicus, adhesions were encountered, and the cecum was located to which was attached a gangrenous appendix. The adhesions were broken up and the appendix ligated, removed and the stump inverted. There was a small amount of thin flakey fluid in this region. No drainage. Wound closed in usual manner.

CASE IV.—J. S., male, 39 years of age, driver, was brought to the Methodist Episcopal Hospital, service of Dr. Chas. H. Goodrich, July 26, 1914, complaining of pain across the middle of the abdomen. Family history, irrelevant. Past history, irrelevant. Present complaint: Three days before admission, the patient was suddenly seized with severe cramp-like pains, worse on walking, located in the umbilical region. A few hours after onset, the patient vomited a small amount of undigested food. He had never experienced a similar attack. The bowels have been slightly constipated. The patient is a well nourished adult male, appears ill, face apathetic, lies with the knees drawn up, seems to be in pain. Mouth contains carious teeth. Cardiac and respiratory systems negative. The abdomen shows marked rigidity and tenderness over the upper right Rectus muscle and epigastrium. Right iliac region slightly rigid. Point of maximum tenderness two inches to the right and one inch below the navel. Pulse, 120; temperature, 103° F.; respirations, 28. The blood count showed 25,000 leucocytes, 89 per cent. polynuclear cells. A diagnosis of appendicitis was made, with a possibility of a gall-bladder condition.

Operation by Dr. C. A. Anderson. A three inch right Rectus incision, center opposite the level of the umbilicus. Upon opening the peritoneum a large amount of seropurulent material gushed forth. The right iliac fossa was explored and no cecum was found. The pelvis was filled with seropurulent material. The hand was next passed upward and a mass encountered which proved to be the tip of the appendix surrounded with omentum. The incision was lengthened to the lower border of the ribs. The appendix was traced upward to a point just beneath the gall bladder, then downward toward the median line. Its base lay about one inch above and one and one-half inches to the right of the umbilicus. The appendix was ligated and base cauterized. The organ was gangrenous and the tip was perforated. A cigarette drain was introduced down to the base of the appendix, emerging from the upper angle of the wound and a rubber tube with gauze strip was introduced into the pelvis emerging from the lower angle.

The patient had a stormy convalescence for the first few days. The temperature and pulse reached normal on the ninth day and remained there with slight fluctuations. The wound discharged a very large amount of purulent material. The cigarette drain was removed on the fifth day and replaced by a small rubber tube. The upper tube was taken out on the fourteenth day and the lower tube on the twenty-second day. The wound healed slowly, but at the end of the forty-second day he was discharged from the hospital.

The patient was examined Dec. 10, 1914. He stated that he never felt better. He looked robust. There was a ventral hernia at the site of drainage.

The x-ray plate taken Dec. 5, 1914, by Dr. W. H. Wallace shows a partial non-descent of the cecum.

As regards the frequency of complete non-descent of the cecum with total absence of the ascending colon, the post-mortem examinations of Treves undertaken for abdominal research indicate its presence in about 2 per cent. of cases. Partial non-descent with an ascending colon less than 6 inches long was observed in about 7 per cent. The abnormality is twice as common in males as in females. In case of complete non-descent the ileum usually enters the cecum on its under aspect and somewhat posteriorly. The appendix lies under the liver to the right of the gall-bladder.

Both of Treves' cases were in men, aged 41 and 74. In both the cecum was immediately beneath the liver to the right of the gall-bladder. It was horizontal and continued the axis of the transverse colon. The appendix came off the posterior aspect of the cecum. The remaining viscera were normal.

Fahrenholdt found the cecum of a cadaver in the right hypochondrium in close proximity to the gall-bladder. The appendix was normal and pointed downward.

Hartman has described a specimen in a male, age 50, in which the cecum was situated beneath the liver to the right of the gall-bladder. The small in-

testine occupied the right flank. The ascending colon entered the cecum perpendicularly.

Debert has reported a rudimentary cecum continuous with the transverse colon without trace of an appendix.

Lockwood has described two specimens of non-descent in which the cecum was in right hypochondrium directly under the liver.

Robinson reports twelve cases encountered in 130 autopsies. Two were complete, ten showed various degrees of partial descent. The average length of the ascending colon was 6 inches.

Border has reported a case similar to the writers, in the person of M. H., male, age 26, butcher, operated upon for acute appendicitis. The cecum was very short, extended to the right and but little beyond the ileocecal junction. The ascending colon was absent. The cecum which merged into the transverse colon was in apposition with the liver. The ileum entered the large intestines at a right angle and somewhat posteriorly. The appendix was post-peritoneal, gangrenous, and lay coiled up behind

A rotation of the mesentery occurs because of the more rapid growth of the small intestine. The colon lies entirely to the left of the mid-line, and rotates about its mesenteric axis. The cecum enlarges and crossing the descending duodenum passes to the subhepatic position (fourth month) and later descends to the right iliac fossa.

This knowledge of the various phases of the developmental period clears up conditions which may exist at operation, and explains the failure to find the appendix in the usual location. Failure of the colon to rotate may be looked upon as probable when the small intestines occupy the right iliac fossa and when no colon is on the right side. Positive evidence of failure to rotate is indicated by a movable duodenum which has a mesentery and merges directly into the jejunum uncovered by the transverse colon or its mesentery. Failure of the colon to rotate must be considered in determining the diagnosis of obscure abdominal lesions as being a possible cause for mid-pelvic or left-sided inflammatory conditions. Particular attention should be

Fig. 2.—Three successive stages of the digestive tube and the mesenteries in the human fetus: 1. Stomach; 2, duodenum; 3, small intestine; 4, colon; 5, vitelline duct; 6, cecum; 7, great omentum; B, mesoduodenum; 9, mesentery; 10, mesocolon (modified from Tourneux).

the cecum in the fossa to the right of the duodenum and over the kidney.

George R. Fowler observed three instances with corresponding malposition of the appendix in a series of 140 operative cases reported in 1893. Two occurred in males.

As regards the embryology of this condition (see Fig. 2) the primitive gastrointestinal canal is represented by a tube, connected to the spine by peritoneum. The stomach bud first appears in the proximal portion as a bulbous dilatation. The distal portion of the tube later becomes the descending colon, the sigmoid and the left part of the transverse colon. The inferior mesenteric artery supplies this portion. From a portion of the primitive tube between the proximal and distal parts, another small bud appears at about its middle which represents the developing cecum. The distal colonic section enlarges and grows slowly as compared with the proximal section. The small intestine also has its origin from the proximal portion of the primitive tube. The mid-section of the primitive tube has a common mesentery and derives its blood supply from the superior mesenteric artery.

accorded to the possibility of aberrant positions of the appendix in atypical cases of appendicitis. The condition should be differentiated especially from diverticulitis and malignancy.

Bearing these points in mind the preoperative diagnosis will be made more frequently. During 1910-12 the Mayos have observed five cases in which the colon had failed to rotate. In one only was the diagnosis made before operation. A larger percentage of accurate diagnoses should be made, in chronic cases. These should be subjected to gastrointestinal radiography.

Points which aid in determining the exact preoperative lesion are: 1. Signs and symptoms of pelvic, left-sided, subhepatic or retrocecal appendicitis. 2. Difference in the colonic percussion note. 3. Gastrointestinal radiography when time and opportunity permit.

280 JEFFERSON AVENUE.

THE FAIR FACE OF NATURE.

BY WILLIAM D. CUNNINGHAM, A.M., M.D.,
 NEW YORK.

EVEN the homeliest human countenance, irradiated with the reflection of a virtuous mind, is a wonderfully attractive picture. It is rare indeed that nature does not mitigate the repellant elements of her occasionally defective handiwork by the conspicuous commingling of a brilliant exception. Lustrous eyes redeem a monstrous nose. The sheen of a perfect skin effectually covers a number of anatomical sins. It is borne in upon us that nature even in her most whimsical aberrations is striving for an impressive symmetry and will compensate in one direction for the error made in another. Hence it is a matter of common report that certain men of unattractive visage are extraordinarily winsome. They are frequently gifted with the most soothing qualities of voice and expression, rendering their presence welcome to the sick and troubled. They are sometimes orators of a strongly magnetic type completely effacing (witticism unintentional) all disagreeable impressions of structural defect by the compelling attributes of natural eloquence. It is a notable fact that homely women find favor in the eyes of many men, for many such women are married. We are all aware of the welcome accorded certain "plain" girls at social gatherings because of their engaging manners. The term "engaging" is frequently applicable in its literal sense for they are apt to contract matrimonial alliances more expeditiously than their better favored but less agreeable sisters. The fair face of nature is marvelously alluring even in its apparent vagaries. The sun shining upon the craggy heights is sublime and inspiring. The same sun shining on the peaceful and trim-cut valley is equally entrancing. Aside from the purely esthetic consideration of the face let us remember its wonderful efficiency as a piece of mechanical engineering. No stone crusher ever devised possesses relatively one tithe the force of the human jaws. No nicely adjusted mechanical contrivance ever approached the precision and delicacy of the human eye.

All in all there is so much to extort admiration in the contemplation of the most ordinary face that it transcends understanding why any rational being will be guilty of the folly of deliberately marring it. And this marring is done on the imbecile impulse of improving it. "To gild refined gold, to paint the lily, to throw a perfume on the violet. . . is wasteful and ridiculous excess." And the bard of Avon might have added, "To dull the mirror of the soul with daubs of garish paint is hideous desecration." Conceive the hardihood of seeking to supplant the natural hue of health with that compounded by the bungling hand of man! Conceive the consummate conceit of attempting such an outrage! And yet this foolish, impudent, and abortive practice is so prevalent among the females of every community that it might be styled almost universal. I have made a very sweeping assertion, but it is easy of corroboration on every side. Not only are the completed results in evidence in ballroom, parlor, church, and public conveyance, but even the method of application is brazenly displayed by certain shameless habitués in utter disregard of the comment of the onlookers. You and I have seen a woman powder her nose in a street car. We have seen her rouge her cheeks as boldly. As to the finished works of art that flaunt their pink and white enamel in haughty defiance of adverse opinion they are so numerous as to arouse only a languid repulsion.

It is a curious commentary on the whole wretched business that as men emerge from savagery they cease to adorn themselves with paint and women begin to resort to it! Whether this has anything to do with the mental development of the sexes or with an altered perspective of sexual attraction is a problem with which we are not immediately concerned. But we are immediately concerned with the damaging results to the skin of this survival of barbarism. It is a self-evident proposition that if nature intended the epidermis to be smeared with cosmetics, it would have provided the means of elaborating them in the cutaneous follicles. The sebaceous glands are there to provide a lubricant, coursing through the corium are the pink tinting capillaries, and spangling the rete are the pigment granules that give to the varied races their distinctive hue. But never a trace is there of a paint-producing plant. No provision is there for coloring the cheeks but the flash of a healthy circulation. Every artificial expedient to counterfeit the beauty of nature's touch is liable to arouse a rebuking reaction more disfiguring than the trivial defect that it was designed to hide. A chronic dermatitis is inevitable from the continual closure of the sweat and sebaceous glands. Retained secretion accumulates and the frustrated efforts at expulsion arouse a low-grade inflammation characterized by thickening and roughening of the skin and the development of acne. Besides the purely obstructive effects of such applications they possess in most instances an irritating quality of their own that aggravates the evil. If they are composed (as many are) of mineral dyes the danger of systemic poisoning from prolonged absorption is to be gravely reckoned with. The skin of the habitual user of cosmetics, when it is possible to get a glimpse of it at all, is dry, harsh, and coarse. Its natural lines are deepened by the precipitation into them of the solid constituents of the preparation employed. Its pores are visible and usually conspicuous. From prolonged abuse of its delicate fabric it takes on the repulsive aspect of precocious degeneration, so that at thirty when a

woman's comeliness should be in full luxuriance, the bloom and rondure of health give place to the seamed and haggard mask of menacing senility. As in every other interference with the normal operations of nature, absolute dependence must soon be placed upon the artificial substitute. Those who will not undergo the inconvenience of rational dieting and adequate exercise will be forced to depend on medicinally induced defecation. Those whose nervous systems have been long habituated to alcoholic stimulation, may not forego their deleterious indulgence without cataclysmic developments. The smoker deprived of his narcotic becomes a restless, reckless wreck oblivious of every consideration but the gratification of his desire. So the skin, that has been put to unnatural uses, that has been made a mere parchment backing for the decorator's brush, that has been long deprived of its privilege of basking in the sunlight and feeling the reviving influence of the heaven-born breezes, that has been loaded with cloying, clogging, clammy messes until the vitality has been squeezed out of it, presents all the evidences of fettered function and can no longer be made presentable save by continual recourse to the abuse that has been its ruin. The possessor has become and must continue to be a living sham, subject to all the misconstructions that irresponsible tongues may idly or viciously put upon her weakness. For there is no question that many virtuous women paint, under the absurd delusion that they are improving on God's handiwork and magnifying their natural attractiveness. Neither is there any question to what class the casual observer mentally assigns these misguided meddlers. Phryne and Phyllis meet upon the common ground of ruthless, useless vandalism, and cannot hope for charitable distinctions.

It is a suggestive fact that a large preponderance of the cases of acne occur in women. Other skin diseases are distributed with some attempt at impartiality, but acne is by long odds a female affliction. There must be a reason for this. The economic equality of the sexes in the industrial world makes the disproportion more glaring, for it cannot be pretended that difference of occupation is responsible. Men and women do the same sort of office work and the same sort of factory work, and live under the same conditions, and yet the one sex is relatively free from what is virtually an obsession with the other. There must be some factor or factors determining this discrimination. What are the two things that women do and men eschew? Both have practically the same vices of eating and drinking, and both subsist in the same unhygienic environment, but only women paint their faces and distort their forms with corsets. Herein lies the crux of the whole divergence. It is objected that the wearing of corsets is not confined to women, but we are not interested in the foppish simulacra of men who ape the ways of women. We are speaking of clean-cut and unimpeachable illustrations of the two grand divisions of the race. Hybrids and degenerates cannot be put in either category, exhibiting as they do the evil propensities of both. The corset produces enteroptosis and this produces intestinal stasis, whence arises constipation with its mischievous action on the skin. To this proposition there is no dissent. That is to say, there is no dissent among men. Those who are guided by inordinate vanity to torture their forms into what they foolishly consider more alluring outlines, vehemently (to a woman) deny the injurious conse-

quences of the wretched practice. And yet it is an open secret that after eating a reasonably hearty meal they seek the first opportunity to loosen the tormenting harness and give their viscera a chance to functionate. In a flash comes the retort (for women are particularly jealous of the privilege of deforming themselves) that men are also the victims of enteroptosis. Conceded, but to a very much less extent. It is not contended that the corset is the *only* cause of this abnormality. Obesity, gluttony, sloth, and structural defects are contributory in both sexes; but in the one sex the universal surrender to the seductions of vanity adds a factor directly and especially pernicious. This is not written with the delusion of inducing women to abandon the corset. Mighty men have thundered against it with the fervid eloquence of the inspired crusader, only to be met with the contemptuous indifference of the complacent offender who "would sooner be dead than out of the fashion." Love has been styled the "sublime folly of woman." I think that the corset deserves that distinction. There are some women who do not love foolishly. There are some who love very wisely and very craftily. In that particular regard they frequently display a depth of resource and resolution inconceivable to the average male understanding. But in the matter of the beloved corset they are of one mind. It is significant that the pulpit does not take a hand in the argument. One or two enthusiastic divines have attempted, within the memory of man, to shake the adamantine will of woman on the grounds that the corset injured her health, distorted God's handiwork, and by emphasizing her natural physical peculiarities tended to the aggravation of male concupiscence. Those misguided men are dead and their graves are unknown. Their followers in the ministry to-day realize that if they wish to keep the women in the church they must admit the corset also. While every one of the objections cited is just as cogent as it ever was, they are dissipated like a puff of wind before the unbroken front of fashion's cohorts who would give up their church before their corset. So while constrained to state the case against this engine of destruction, it is only to complete the record and round out the etiology. The futility of treatment by removal of the cause is freely conceded. The cause is irremovable. A famous corset house in its advertisement says, "The average woman cares more for her figure than for her health." Cosmetics and constipation, devils twain in the disfigurement of the female countenance, are to be exorcised by different methods of attack. As we have seen, the prevalence of constipation among females is due to the throttling of the struggling viscera by the form-moulding corset. Forced by an insuperable resistance to concede the corset we are driven to expedients for the mitigation of its evil consequences that are wretchedly ineffective, and in the very nature of things interminable. We are at a tremendous disadvantage in this, for vanity is working against us. We must be content with whatever half success we may achieve.

But with regard to cosmetics, a vigorous presentation of their injurious action on the skin may arouse vanity in support of our position. Let us persuade the face painters that instead of enhancing their beauty they are rapidly destroying it and the very pertinacity that will hold a woman on a dangerous course because it is attractive from the esthetic side, will hold her from it if that opinion can be altered. It is possible, therefore, to enlist in

our service the very quality that it is impossible to subdue. The *a priori* reasoning that cosmetics are deleterious to the skin because they are foreign bodies interfering with its necessary activities, is sustained by the lessons of experience. Those who paint to improve their appearance soon paint to preserve it. What was a weak surrender to a yearning for admiration, becomes a stern necessity to hide augmenting ugliness. The wan and haggard hue of the unpainted actress is in startling contrast to that of the tinted Venus flaunting her manufactured charms in the glare of the spot light. We wonder at her marvelous pulchritude, forgetting in the fascination of the moment the sordid manner of its production. We do not see her in the abandon of her home, where, with her deceptive adjuvants laid aside, she comes perilously near to the fulfillment of Hamlet's prophecy when in apostrophizing the skull of Yorick he exclaims: "Now get you to my lady's chamber and tell her, let her paint an inch thick, to this favor she must come." Yet sometimes this actress has a keener appreciation of the fitness of things than her "lay" sister and confines her facial decoration strictly to the demands of business, thereby limiting the damage to her integument in a very material degree. And still the damage to her integument is manifest in the unwholesome aspect of the steady user of make-up. The same unwholesome aspect would be discernible in the unprofessional users of make-up if it were possible to catch them in a moment of unpreparedness. But the necessity born of their vanity keeps them ever on the alert and opportunities to see beneath the surface are rarely afforded. Such opportunities, however, are occasionally vouchsafed the physician who may be called in the stress of acute illness, or may be consulted for the disfigurement resulting from the persistent abuse of the skin. As noted in passing, one of the most annoying and conspicuous varieties of this unfavorable cutaneous reaction, is acne. Every physician is familiar with the preternatural perversity of this reproach of dermatology. Once established its obstinacy might very soberly be termed malignant. The puerile inefficacy of the best esteemed plans of treatment is notorious. Attention to the bowels and diet and prodigal profusion in the use of lotioalba, may be maintained for months and even years without mastering the exasperating pest. Some of this ill success is due no doubt to the unsteadiness of the patient who will not be true to herself and will violate the rules laid down for her guidance. She will eat sweets and and sweetly deny it. Why patients will palter with their own interests and strain against the regulations made to help them is a problem of which we have no solution. The late Edward G. Janeway was heard to remark "Never believe anything a patient says unless he can prove it." This was drawing it rather strong, but it undoubtedly was an intentional overstatement, for the sake of emphasis, of the unreliability of the average clinical history. But we cannot hope to make people over and must deal with them as they are, not as we would wish them to be. From this viewpoint acne is a therapeutic fiasco. Here again startling exceptions may arise to discredit our prognostics; but taken fore and bye the proposition holds. So it is prudent for the woman who is tempted "to paint the lily" to pause and weigh the consequences. If she excites a revolt in her sebaceous glands she will pay an enormous price for her audacity. She will be confronted by conditions that paint will not hide. She may tint the

little hillocks any shade she will, but they will persist in their unlovely contour still. She will be inevitably convicted of "having pimples." And this will come about irrespective of the composition of the favorite powder, paste, or cream of the seeker of the beautiful. Some of them exercise a peculiar malinfluence of their own, but all of them, even the most highly commended and "harmless skin foods" obstruct the excretory function of the normal integument and thereby tend to the production of various dermatoses.

It is asserted in defense of the practice of "making up" that many of the preparations employed are of the same character as those recommended by eminent dermatologists and therefore cannot be detrimental to the skin. This is a vicious and insidious half truth which is often more misleading than a downright lie. The truth is that dermatologists do prescribe zinc, and bismuth, and calamine, and lanoline, and the stearates, and the glycerites, and sundry other ingredients appropriated by the exploiters of cosmetics. But the falsehood consists in insinuating that dermatologists prescribe these things for a normal skin. Dermatologists do not treat the normal skin. They have to do with abnormal conditions only, where the problem is to get rid of a pathological process and not paint a picture. It is clear that applications may be justified to remove disease which would be highly improper if no disease existed. Therefore this plea of the "beauty doctors" to the indictment drawn by the physician is disingenuous and incompetent. The public should be warned against its specious sophistry. The prescriptions of eminent practitioners may be quoted to demonstrate the innocuousness of certain advertised formulas, but they will not be accompanied by a description of the "diseased" conditions for which they were compounded. The array of "skin foods" enamels, bleaches, powders, rouges, and other decorative expedients, designed for the transformation of homely countenances, has no place in the armamentarium of the ethical physician. His purpose is to restore damaged tissues to the normal, not to damage normal tissues for the gratification of a perverse pride. The development of acne as we have ascertained is much more frequent in women than in men because of the twin evils—cosmetics and constipation. The rôle of cosmetics in this relation is a general one, acting mechanically to clog the orifices of the sebaceous glands and prevent the regular extrusion of their contents. Some of them add an element of active irritation, and induce a complicating dermatitis. This may take the acute form under certain circumstances and spread far beyond the actual area selected for embellishment. The chest, back, and arms of the fashionable beauty in evening attire are as palpably artificial as any sculptured bust or plaster of Paris imitation. Perhaps this is a woman's instinctive concession to modesty in actually concealing what she is pretending to display. Such a broad expanse of enamel will yield a corresponding expanse of dermatitis, if it is plastered on a susceptible subject. But even when confined to the face its radius of reaction may be wide, the irritant being carried by the fingers to remote localities or reaching them through the medium of the circulation.

This latter possibility furnishes food for serious consideration, since it removes the objectionable applications from the narrow and comparatively unimportant sphere of local operation to the broader

and graver one of systemic poisoning. When we reflect that arsenic, antimony, mercury, and lead enter into the composition of many of the cosmetics, and that under the influence of heat the fatty secretion of the skin converts them into readily absorbable compounds, we are no longer confronted with the triviality of a ruined complexion but with the threat of a chronic intoxication. The results of the latter vary with the identity of the mineral involved. It will not be derogatory to the intelligence of the physician to remind him of the destructive action of lead on the nervous system. The colicky pains and peripheral neuritis with wrist and toe drop, the crippling arthralgia, and the obstinate constipation all point unerringly in the one direction. Associated with these is an anemia of the profoundest type. The kidneys take on the cirrhotic changes peculiar to arteriosclerosis. There may be involvement of the central nervous system with hebétude, amnesia, or even coma and convulsions.

There is no means of predicting who will reveal the unfortunate susceptibility that will speedily bring on this train of consequences. Any woman who blindly daubs her skin with a cosmetic of unknown composition runs the risk of a long period of ill health and torture; perhaps of permanent disability or death. There is no conjecture about this. The melancholy fate of many painters and plumbers and other manipulators of lead is a matter of record. A celebrated clinician has related the history of a man who was accustomed to take a glass of ale early in the morning at a certain saloon of which he was the first customer. After a while he began to show signs of plumbism and the manner of invasion was for a long time undiscoverable. Finally by a minute investigation of all his actions during the day this matutinal drink of his was brought to light. Cross examination elicited the suggestive circumstance that the barkeeper did not throw away the first beer drawn but handed his unsuspecting patron the fluid that had been in the lead pipes over night. The carbonic acid had made a carbonate with the surrounding lead, and this decoction had been swallowed by the patient morning after morning, and had gradually poisoned him. To be sure, the amount of lead in each glass was very small, but that emphasizes the point we are seeking to make with regard to cosmetics, namely that the continuous absorption of minute quantities eventually overcomes the eliminative powers of the victim and induces a chronic toxemia. Some subjects are so readily affected by this particular agent that the penetration of the skin is not essential. The inhalation of the infinitesimal amount possible from an application to the face is competent to exert a destructive action on the blood and nervous system if sufficiently prolonged.

Arsenical combinations are particularly injurious to the skin, for arsenic is a decided irritant and tends to excite in any proportions a corresponding degree of dermatitis. The fearful fulness of its power is seen in the reaction to Marsden's paste applied for epithelioma. It induces a deep slough in an extensive area of violent inflammation. In lesser concentration arsenic will be attended by less stormy results. But in any proportion it is by its very nature a cutaneous irritant. The usual interference with circulation and excretion, caused by the menstruum in which it is incorporated, intensifies its destructive action. The tendency of living tissue to resist attack is checked by the pressure of the incommencing paste or paint. Bartholow says:

"Weak applications of arsenic may excite dangerous symptoms by diffusion into the blood. Numerous instances have occurred in which wall papers colored with arsenical pigments have poisoned the occupants of an apartment. Garments covered with aniline dyes, fixed by arsenical mordants, have induced local ulcerations, and systemic symptoms from absorption of arsenic. Applications to a large portion of even the unbroken integument, have, in numerous instances, excited dangerous symptoms and have produced fatal results." It naturally follows from the foregoing that the persistent coating of the integument, sometimes over quite extensive areas, with a concoction of arsenic is liable to entail a very serious penalty. Nausea, vomiting, diarrhea, gastralgia, palpitation of the heart, dyspnea, albuminuria, and edema are among the general disturbances frequently observed. Puffiness of the eyelids is quite characteristic of arsenical overdosing and indicates concomitant involvement of the kidney.

The distinctive cutaneous developments following the absorption of arsenic are a yellowish brown or mahogany pigmentation and a keratosis of the palms and soles. The hair follicles escape at first and stand out in sharp contrast to the surrounding discoloration. This produces a delicate lace-tracery effect that is quite fetching both in an esthetic and a diagnostic sense. The pigmentation gradually obliterates this design and becomes general over the affected surface. It is apt to be very widespread and persistent. It may be induced by trivial doses in those predisposed. In fact it is astonishing to find that a few drops of Fowler's solution have been thus prodigal of mischief. The color may endure for months and even years after the cause is abandoned. The keratosis of the palms and soles may become of the most aggravated type, persisting long after the drug is withdrawn. It has not infrequently been the starting point of epithelioma. This deplorable sequel is now regarded as more or less imminent in any such case over forty. It is reasonably certain that some cases of herpes zoster are attributable to the administration of arsenic or its absorption through the skin. This is a fair assumption when we consider the competency of the drug to produce peripheral neuritis. There is no incongruity between an attack from the same cause on the terminal nerve filaments and an attack on a posterior nerve root.

Other dermatoses, of lesser obduracy but nevertheless distressing and disfiguring, have been observed in the course of arsenical medication. They may be erythematous, papular, vesicular, bullous, scarlatiniform, morbiliform, petechial, desquamatory, or even gangrenous. Like other drug eruptions, these various manifestations represent intensity of intoxication or individual susceptibility.

Even the laity is possessed of some information regarding the dangers of mercurial poisoning. "Salivation" is a term quite well understood outside medical circles. The liberal dispersion of syphilis has contributed largely to this educational acquisition. Not only the patients but their friends and confidants are acquainted with the untoward effects of injudicious freedom in pushing mercury, for, strange as it may seem, the luetic subject labors under no sense of humiliation, and frequently assumes a swaggering attitude toward his less distinguished associates. He will discourse of his symptoms and the action of remedies to his awestruck not to say envious listeners. Another factor

in the dissemination of this sort of knowledge is the tradition that has carried down to us the methods of the practitioner of fifty years ago in the face of most of his pathological problems. He gave calomel with a liberal hand and for the most diverse conditions. It seemed to be looked upon as a species of talisman, working wonders in an utterly inexplicable way. Naturally the public soon experienced the undesirable consequences of this reckless indiscrimination. Fireside lore outweighs the enlightened tale of history, and, despite the practical abandonment of the freehanded administration of this treacherous drug, the memory of its past exploits is indelibly fixed on the common mind. So it has come to be a popular belief that mercury is a dangerous drug and that its peculiar propensities are to loosen the teeth and lodge in the marrow of the bones, where it makes painful barometric responses to changes in the weather. The loosening of the teeth is an established fact. The retention in the bones is a bit of fable founded on the necrosis that follows chronic poisoning extending over a long time. Marked anemia is a constant consequence of excessive medication or continual absorption.

It is well within the bounds of moderation to assert that the constant employment without medical supervision of topical applications containing such a powerful poison is decidedly imprudent. On diseased surfaces it is possible to use preparations of a strength utterly inadmissible on the normal skin. Note the freedom with which ammoniated mercury ointment is rubbed into patches of psoriasis and also note the rapidity of its systemic action when syphilis is treated by inunction. Constant contact with the least penetrating salts of mercury will sooner or later break down the epidermal barrier and permit of the invasion of the circulation. The dermatitis that is aroused by the bichloride is not only distressing and unsightly but leaves breaches for the entrance of this least readily absorbed of the aforementioned salts. It is never possible to forecast an idiosyncrasy. Until the damage is done we can only administer the general caution, "be careful." We know that some of the users of the mineral dyes, bleaches, or varnishes are going to get a disagreeable surprise. In the absence of signs for the detection of the susceptible, it is sound sense and good strategy for all to avoid the risk.

The salts of antimony are cutaneous irritants like the others and, being taken up by the lymphatics, under favoring conditions induce the gastrointestinal irritation and marked enfeeblement characteristic of this poison.

The devotee of fashion with alabaster arms and bust and delicately tinted visage, need well maintain an alimentary canal of unvarying sweetness, else the eructation or other evasion of sulphureted hydrogen may work a marvelous and confounding transformation. It is said that the odor of onions is equally perilous, but this contingency will hardly arise, as onions are not in favor among such refined and gentle natures, especially before a public function.

The toxicity of wood alcohol has been firmly impressed upon the popular comprehension by the newspaper accounts of the disasters that have followed its employment in the manufacture of cheap "whiskey." The term "manufacture" is used advisedly, because instead of being the result of distillation this concoction is made by hand by

the mixing of various ingredients designed to give the taste and appearance of the real liquor. Of this danger from wood alcohol the public has been sufficiently warned. But there is another phase of the subject that has not been duly emphasized. That is the possibility of absorption through a damaged integument in amount adequate for the production of toxemia in those unfortunately predisposed and the probability of the excitation of a distressing dermatitis in any integument exposed to its influence. We see those who use it in the trades, such as painters and wood polishers, frequently attacked by a disabling inflammatory reaction. Those who use it in the "art" of makeup as a menstruum for their enamels are liable to the same disagreeable experience. And it is certain that the tradesmen engaged in the manufacture of such objectionable products are not above the unconscionable substitution of the cheap and dangerous variety of alcohol for that distilled from grain. Here is a situation that is big with peril for the vain or vicious victim of a yearning for unmerited admiration. A dermatitis once provoked may prove extremely intractable, and may leave the skin more vulnerable to the attacks of other irritants. Not only that, but the skin may never regain its former tone, some degree of harshness and aridity persisting as a consequence of the violence to which it has been subjected.

Realizing the utter futility of the appeal to reason in the matter of the corset, we are not fatuous enough to expect any fuller response in the matter of cosmetics. Our gravest warnings against the poisonous effects of many of these would be flat and impotent, were it not for the fortunate circumstance that injury to the health is accompanied by injury to the complexion. The dread of this direful possibility should give the painter pause. For here is no trivial question of the maintenance of the normal function of the vital viscera and the prolongation of vigorous existence, but the transcendent consideration of the preservation of female seductiveness. Fashion inculcates a calm contempt for every argument based on physical well-being; its only goal is physical well-seeming. It is the art of allurements. Every opposing contention, no matter how serious and well sustained, is airily waved aside as wholly inconsequential. We are not pettishly scolding about something we cannot mend. We are stating a situation to which we have to yield, but which we hope to turn to the advantage of our sisters in spite of themselves. If we can succeed in convincing them that the use of cosmetics, instead of improving their appearance, rapidly and permanently spoils it; if we can succeed in aligning on our side the love of admiration that brooks no opposition, that rides roughshod over every plea of bodily health and religious duty, we shall have effectually disposed of one of the causes mercilessly marring the fair face of nature.

616 MADISON AVENUE.

Orange Peel as a Laxative.—Rosenthal recommends the following: Fresh orange peel is boiled for half an hour in water. This first very bitter infusion is thrown away or utilized for washing or for the teeth. The peel is then boiled a second time for 30 minutes in slightly sugared water and afterwards spread out to dry. It is then ready for use. The peel of a single orange forms a sufficient dose to excite the evacuation of the intestine, but this evacuation is not purely mechanical. It is accompanied by a flow of bile of variable amount, and this biliary activity continues for several hours.—*The Lancet*.

NEUROTIC MANIFESTATIONS IN CHILDREN.*

BY ADOLPH STERN, A.B., M.D.,

NEW YORK.

In this paper I shall present some phases of the neuroses that occur in children, viewing them especially from the standpoint of etiology and therapy.

Since the symptoms of a neurosis are manifestations of psychic (as a rule, unconscious) processes, it is only by tracing these psychic processes to their source that we can arrive at a rational form of therapy. Psychic phenomena should receive psychic treatment, though at times drugs may be given and other physical agencies used to tide over an acute period. All forms of treatment other than psychic, are purely adjuvants, and useful to meet immediate symptoms only. Through them alone we cannot expect the best of results, for they do not remove the etiological factors present. The well-informed medical man is no longer satisfied to meet surgical conditions with symptomatic therapy only. The various digestive disturbances of a chronic appendicitis are only permanently cured by the removal of the cause, remote though it apparently be.

We analysts attempt the same procedure. Every symptom prompts the question: Why? We attempt to answer this question not by attributing to the causation of the symptoms a general etiology, but by seeking, as the tendency now is in psychiatry and in the neuroses of adults, an individual psychological etiology and removing it. Unfortunately we are not always successful, so very many and at times diverse factors entering into consideration. Nor can the surgeon invariably claim success with every patient suffering from appendicitis on whom he operates. We do not, however, on that account decry the operation of appendectomy.

In the treatment of the neuroses of children we are enabled to make "short cuts," being, as we shall see from the patients' histories, enabled to get at the source of the trouble quite readily. The psychic processes of these little ones are not very involved. Nor is there present the vast amount of repressed emotional material to uncover that exists in the case of adults; moreover, I believe that children are less inclined than adults to disguise their desires or impulses. All these factors warrant us in expecting more rapid results in the treatment of the neuroses of children than of adults.

I shall detail the histories of three patients, illustrating as many aspects of neurotic manifestations. In the first patient described I have analyzed the psychic processes and am reporting them sufficiently in detail to show the etiological factors concerned in the formation of the neurosis. In the other two patients no analysis was attempted, the therapeutic measures being instituted, so to speak, empirically, basing the treatment on the knowledge gained from the analysis of adult neurotics.

Let us now go into the history of these little patients and see to what extent they bear out my prefacing remarks.

CASE I.—The first case is that of Elsie S. She is the fourth of a family of five children, and the favorite daughter of a markedly neurotic mother. She is of a retiring, bashful, reticent disposition, given to day dreams. She is a bright child, of Russian parentage,

*The cases here reported are patients from the Neurological Clinic of Dr. B. Rosenbluth, Mt. Sinai Hospital Dispensary. I hereby express my appreciation for his courtesy in permitting their publication.

only three years in this country, but in no way behind in her studies on that account.

This little patient was referred to us in February, 1915, with the diagnosis of epilepsy. When first seen by me, she had been suffering for two months with nocturnal attacks of pain and "drawing" sensations in the left side of the face, followed, after these had lasted for a varying length of time, by unconsciousness of ten to thirty minutes' duration. The pain and spasm ("drawing") always occurred in the left cheek; at no time were convulsions or loss of sphincteric control present. During the unconscious state the patient could hear but apparently not understand what was said; could see but not recognize people, and was unable to talk.

The first attack consisted of pain and a drawing sensation in the left cheek. The second attack, two weeks later, consisted of pain and spasm, followed by unconsciousness. During the third attack of pain, an older sister, with whom our patient slept, pressed her cheek to that of the child. The attack (pain, drawing, and unconsciousness) was thereby diminished both in duration and intensity. The succeeding attacks were ameliorated in the same way, until early one morning, when the patient had a "spell," and finding that her sister had already risen, she jumped out of her bed and ran to that of her mother, threw herself over the body of the latter, and then fell to the floor in a faint. The unconsciousness this time lasted about half an hour. All the following attacks were similar to the one just described. Up to the time I saw the patient there had occurred eight attacks.

One can picture to himself the anxiety in the immediate family such "spells" produced, especially in the markedly neurotic mother. During the unconscious state the patient received the solicitude and tender care of her relatives, being rubbed with cold water and alcohol, etc., and exhorted and entreated to speak, and "wake up." After "coming to," she was placed tenderly in bed.

To the psychoanalyst (and I feel sure ere long others would be likewise impressed) the outbreak of a neurosis represents an unsuccessful solution of a problem with which the patient has come face to face. He solves it to the best of his ability, being unable to forego that which he desires, and at the same time maintain his emotional equilibrium. The difficulty is overcome, but at the cost of a neurosis. This is true of adults, as proven by analysis, and the same holds true of children.

A thorough local and general physical examination proving negative, and diagnosing the case as a functional neurosis (hysteria), I directed my efforts to the emotional sphere in an attempt to find the cause of the disturbance. On close inquiry I learned from the patient that for some months before she came under my care she had realized that her sister, with whom she slept, had a suitor. The fiancé of her sister was no favorite with our little patient, nor was the husband of the oldest sister, on the occasion of whose marriage the patient felt that she had "lost" a sister. The brother-in-law was strongly disliked for taking the sister away. These same emotions (jealousy, hate, depression) were again aroused in Elsie when she learned that her sister was in love; these same emotions were intensified when, about one week before the onset of the neurosis, the engagement was announced. The patient felt very keenly that she was "losing" her sister. To the former it appeared that the sister was going away, was leaving the patient, who did not realize that a sister is a sister, whether married or single. If, however, we place ourselves in the position of our patient in her attitude toward her sister, we see very readily that to Elsie the older one stood in the light of a sister plus something more, and it was this "something more" that our little patient was losing, and not her sister. What is the added factor which looms so large in the eyes of our patient? To my mind, the added factor spells love, or lover, to the loss of which the patient could not adjust herself. Naturally this lover-like attitude carried with it a feeling of enmity toward her future brother-in-law, who deprived the patient of that which she herself so much desired. Our patient did not (nor does any neurotic) consciously realize that her attitude to her sister was that of a lover, nor were her symptoms consciously brought about. Yet to the one who seeks, she betrayed by means of her symptoms that which she attempted to hide.

Since then Elsie felt that her sister was "leaving" her, an attempt on her part to prevent that separation

is only a natural impulse.' Or if a separation be inevitable, an attempt on the part of the patient to make the most of the time that still existed before the separation actually took place naturally follows. The child sought to accomplish this by becoming sick; if she could not stop the marriage, at least she could get, through sickness, some attention from her sister that she could not if she were well; and when, during an attack, the loved object was absent, the mother or the rest of the family³ was chosen to make up in part at least (by means of attention and solicitude) that which she sought, but could not at the moment obtain, from her sister. This brought about the second phase of the illness—the jumping from her bed and fainting on the floor.

I have attempted to show, step by step, the mechanism of the neurotic manifestations, connecting them with their causes. Naturally steps for curing them are instituted with the etiological factors in view.

The sister being responsible for the first phase of Elsie's illness, we readily remove this cause by having the patient sleep in a separate room. The second phase (jumping out of bed and fainting) is a more difficult problem. Any one who has attempted to urge a fond, morbidly anxious, neurotic mother to pay no heed whatsoever to her child when in a faint can very easily understand the difficulties I had to overcome. Patient persistence will, however, achieve results, as it did in this case. I urged the mother, and incidentally the rest of the family, to pay no attention to the child when in this condition—apparently to neglect it.

To the patient, a very intelligent child, I explained that her sister, whether single or married, was still her sister, and that the marriage of the latter in no way changed the relationship that previously existed between them.

No direct medication to control the "attacks" was administered. As a placebo, small quantities of a rhubarb and soda mixture were given.

During the first month that I saw Elsie she had three attacks; in the next month only one, one in the third month, and none since.

The second case is typical of a very common form of neurosis, usually misnamed and treated as chorea. I do not refer to tics, or habit spasms, for these are very easily distinguished from Sydenham's chorea. The differentiation (from chorea) of the neurosis I have in mind lies in the picture as a whole rather than in any particular symptom. Some of the important differences are as follows: In the neurosis no temperature is present and no endocarditis develops; those children suffering from the neurosis are often sick for months or even years with remissions or exacerbations of the malady rather than true new attacks or intermissions. Sydenham's chorea comes on usually in the spring, and its duration is from six weeks to three months. In the description of chorea most authors lay stress on the neurotic element present both in the patient and in the family. This is a very important etiological factor, not in true chorea, but in the neurosis, and to my mind aid us greatly in distinguishing Sydenham's chorea from the neurosis. We frequently hear that overstudy, nervous strain, or the presence of other cases of "chorea" among the children precipitates an attack. This is very true, and a very frequent cause, not of Sydenham's chorea, but of the neurosis; for as I have shown in the preceding case (and it is true also of the present case) an outbreak of a neurosis serves the patient a definite purpose.

CASE II.—The patient, R. S., 10 years of age, came under my observation in the out-patient department of the Neurological Clinic of the Mount Sinai Hospital in June, 1914. He is the only child of an elderly father and a young, markedly neurotic mother. The boy had gone through the ordinary diseases of childhood without any sequelæ. Emotionally, even early in life, he showed deviations from the average child. He was self-willed, obstinate, throwing himself on the floor in outbursts of violent temper if denied a wish. To prevent a too frequent repetition of these incidents, the indulgent mother

often acceded to the child's wishes. The patient suffered from nocturnal enuresis between the ages of 6 and 8 years; and also from rectal incontinence, even up to the time he came to me for treatment. This occurred regularly (and also on other occasions) when seeing in the "movies" scenes of violence (fighting, or cowboys riding on horseback). The child had always been "mothered" too much, being at times dressed, and up to the time I first saw him always bathed by his mother. He had always slept in the same room as his parents, and frequently, especially if restless in his sleep, was taken into his parents' bed. This had occurred with increasing frequency in the past three months.

The present history is that for the past two months the child had been more restless at night than usual, could feed and dress himself only with difficulty; that his gait was so clumsy that he frequently tripped, and that his speech was indistinct. A physical examination revealed a well-developed, well-nourished boy (despite the mother's statement that his appetite was poor), with no organic defect. "Choreiform" movements of the limbs and face were present. His gait was awkward. With the child lying prone and his attention distracted, all movements ceased for the time being.

In view of the present condition and the personal and family history, I diagnosed the condition as a neurosis, and not a chorea; and therefore directed the treatment accordingly. A separate sleeping room was ordered, and the parents were not to visit the child at night, even if the child called out or was restless. Moreover, the patient should attend to his own immediate wants, should dress and bathe himself. The medication consisted of small quantities of rhubarb and soda mixture. I did not see the patient again for six weeks. The mother then brought him back, but slightly improved. On inquiry I learned that the child had been sent by another physician into Mt. Sinai Hospital, kept there for four weeks, and then discharged cured. However, immediately on his return home the same symptoms had gradually reappeared, and now, two weeks after his discharge, the child was in the same condition as on admission to the hospital. The mother had brought her child again to the dispensary, that we should send him to the hospital, a procedure involving a minimum of effort on her part.

While the hospital would (and did) bring about an apparent cure, due in my opinion only to the fact that the child was completely isolated from the exciting cause of his neurosis—the home environment—yet contact once more with those surroundings brought about a relapse. The permanence of the cure depends on bringing about in the home of the patient a condition akin to that which obtains in a hospital, where children's whims and fancies are not acceded to, and where no morbid anxiety is manifested over the patient's condition.

The only way this can be accomplished in the home is by obtaining the full cooperation of the mother, for she is the exciting cause in this instance. It took weeks of patient but firm endeavor, always refusing to send the boy to the hospital, before the mother carried out my instructions to the letter. During this time the child's condition remained stationary. It took but one week of "isolation," with only a placebo during all this time, to effect a cure that is permanent to this day.

Surely in this instance we have accomplished more than a cure of the child's symptoms. We have attempted and succeeded in some degree in bringing about a more nearly normal relationship between child and parent, insuring to that child a better prospect for self-reliance than he would otherwise have had, and making the mother realize, perhaps unconsciously, that her boy was growing up and should be treated as a developing being, and not as a perpetual infant.

The next case presents a very important and at the same time a very difficult problem, differing from the two preceding cases in the important respect that this patient is a congenitally mental defective.

CASE III.—The child, V. P., 9 years of age, is the only offspring of neurotic parentage. The mother is a kindly, intelligent, morbidly anxious woman. The father is erratic and overbearing, rather harsh with the

boy. The patient was backward from infancy, acquiring the power to sit, stand, walk, and talk more slowly, and at a later period than normal children.

The mother brought her boy to me because he was, since three to four years of age, in a constant state of apprehension or fear, reacting violently to the least noise or to a raised voice, trembling in his entire body at a cross word or a stern look from his parents or strangers. The child did not go anywhere except when accompanied by the mother, and then literally tied to her, holding her hand or some part of her garment; at home he spends most of his time in her presence. Like the preceding patient, at the time when brought to me, he was bathed, dressed and sometimes fed by his mother. He sleeps quietly (alone in room) and his appetite is good.

An examination reveals a congenitally mental defective child, well nourished. A marked constant lateral nystagmus is present. The patient is restless, not sitting quietly in any one place for any length of time; he is in a constant state of unrest and apprehension,⁵ is good-natured and kindly disposed.

As in the previous case, the treatment was instituted, so to speak, on empiric grounds. No analysis was attempted, the history itself giving me an insight into the etiology of the neurosis—namely, a pathologically strong attachment of the child to the mother and his dependence on her for many things which he should have done at this age for himself. Owing to the mental defect present, developing in this child the ability to look out for himself is, if anything, what is to be sought for. Handicapped emotionally and in mentality, there is little in sight for the boy except a life of absolute dependence either at home or in an institution. The child is far from being uneducable, in a bigger sense than that of merely gaining knowledge. True, the mental defect limits his power of acquiring an education, in the limited sense of the word. But his apprehensive state, the necessity so to speak, to be constantly on the defensive, fearing an attack from some direction, gives him so much to do with himself that it withdraws just that much energy or attention from other fields. This is well illustrated by the following incident:

About one month after I had seen the patient for the first time, the mother told me that, among other things, the boy's memory had improved. She had sent him on an errand and he had fulfilled it. Previously he regularly returned before completing the errand, saying that he had forgotten what had been expected of him. The boy's memory, however, had in reality not improved. I explain the above incident in this way. The child was by this time in a much less apprehensive state, had begun at my direction to do things for himself, to play with other boys, and was attending school in a special class for defectives. He had to some extent, so to speak, forgotten himself, and was adjusting himself to his environment.⁶ There being less need of keeping on the alert to ward off an (imaginary) attack, the child was enabled to look after matters that did not pertain to his apprehensive state, and for that reason "his memory had improved." In the course of three months the child had made great strides toward a normal emotional state and self-dependence. Though one might say that the mother was at fault in bringing about, and especially in maintaining this pathological dependence, one can hardly blame her for her solicitude and too tender care in such an instance. Her ready co-operation, however, following my explanation, showed her instinctive realization of the cause of her child's condition, and to that (cooperation) was due the rapid improvement in the patient.

Summary.—In all the patients we see that the cause of the neurosis is an inability on the part of the individual to adjust himself to his surroundings and at the same time maintain a state of emotional equilibrium. By analytical treatment we attempt to achieve a twofold object. First, a removal of the cause of the symptoms; second, we seek such a change in the individual (and where possible in the environment) that he is enabled to fit into his environment more smoothly than before. This latter phase is by far the more important, for as applied to these children, it places them in a proper attitude toward the members of their family, and as a matter of course toward their environment in general.

For all of us have, in so many instances unfortunately, indelibly stamped on our psyche the impression gained in the family life in our very early youth, and these impressions guide us, for good or ill, in our relations with our fellow-men in later life.

NOTES.

¹ If we assume any conscious intent or malingering on the part of our patients, we do them a gross injustice, and thereby fail to obtain a correct conception of what actually goes on in the individual's unconsciousness. The patient did not consciously realize that her attitude toward her sister was an abnormal one, yet her saying that the marriage of that sister meant her loss, betrayed that some attitude other than a purely sisterly one existed between the two sisters as far as our patient is concerned. I have elsewhere pointed out ("The identity of Peculiar Traits and Neurosis," *N. Y. Med. Journal*, Oct. 16, 1915) that to the normal, the marriage of a brother or a sister means an increase in the number of relatives, rather than the loss of one.

² One of my patients very early in his neurosis said to himself that his sister (who had become engaged just prior to his illness) would surely postpone her marriage till his recovery. The patient did not realize the full significance of this fancy (wish). He did not realize that his saying this to himself, would unconsciously prolong his illness so as to put off the marriage indefinitely.

³ This process represents very nicely what regularly takes place in the treatment of neurotics, and illustrates in a way what we call "transference." In this instance the mother or the rest of the family acts as a substitute for the sister. During the treatment the physician acts in the same rôle. We all know the attachment to, or interest, that so many neurotics show in the physician in the early stage of the treatment, and that this interest very often soon changes to indifference or even hostility. The analyst recognizes the cause for these phenomena, realizing that the patients center their emotions (interest, trust, confidence) in him, and that it is a necessary, though unconscious, process on the part of the patient toward recovery. If circumstances permit, these steps are explained in due time to the patient. In all instances, an attempt is made to have the patient take up outside interests, in this manner effecting as far as possible a separation from the exciting causes of the neurotic attack, enabling the patient, instead of repressing his emotions, to convert them into normal interests. For, to my mind, emotions are manifestations of energy convertible, like heat, light, etc., into other forms of energy.

⁴ For the past four years this child was taken by the mother to the toilet every night, because he was afraid to go alone. Knowing this patient's pathological desire to be with his mother, it is interesting to see how the child unconsciously achieves its object by this procedure. He does not primarily desire to have his mother with him because he is afraid; in reality, he develops the fear primarily so that he can request his mother to accompany him. The desire is to have the mother with him, and as a means to attain that, his fear takes form.

⁵ Fear is, biologically, an instinctive impulse for defense or self-protection. The shrinking, watchful, anxious attitude of our patient, looking with pleading yet distrustful eyes at the examiner, was clearly expressive of an expected attack against which the patient guarded himself. This attitude was constantly present. His only means of protection, however, was by clinging to his mother (dependence).

⁶ His mental effort, which is necessary for all the possible though in his case limited intellectual attainment, is interfered with by his overactive emotional processes—preeminently suspicion and fear, and hence the need for the removal of these impediments to his progress.

120 WEST EIGHTY-SIXTH STREET

Race Degeneracy.—In Boston recently 600 men presented themselves for examination for admittance to the United States Navy, and thirty were accepted, the remainder being rejected as physically below normal or mentally or morally unfitted. From these facts, Rear Admiral Albert Ross, U. S. N., draws the conclusion that we must make men of our rapidly degenerating citizens before we can make sailors or soldiers.—*Journal of the Military Service Institution*.

HOW CAN THE PHYSICIAN'S TOTAL INCOME BE INCREASED?*

By THOMAS F. REILLY, M.D.,

NEW YORK.

PROFESSOR OF APPLIED THERAPEUTICS, MEDICAL DEPARTMENT,
FORDHAM UNIVERSITY, NEW YORK CITY.

I BELIEVE it will be accepted as a fact that a medical society discussion of the economic side of the practice of medicine generally fails to interest the general practitioner and as a consequence he remains at home. This may be attributed to the fact that the usual speaker is an altruistic highbrow, well situated in life from a financial standpoint, or at least putting up such a front—to use a slang but expressive quotation—that one instinctively thinks of society functions, grand opera, etc., when he addresses his fellow practitioners. He discourses on scholastic ideals, and talks platitudes as to the duties of the dear public to the profession, etc., as though the consideration of money was beyond him; after which lecturing he sits back and does nothing, and is perhaps decorated with a society chairmanship or some similar honor.

The public—bless their souls—smile a dry smile and say: "What delightful people doctors are in general, and Doctor X. in particular. Money never enters into a doctor's mind." And the doctors, the real everyday doctors—well, they go home to hard work, long hours, unpaid bills, and duns.

On the other hand, the mercenary extremist constantly aims to make the practice of medicine a purely money-making venture. Midway between these two extremes the bulk of the profession will be found, but the shouters at both ends have obscured the main issue by the clouds of nonsense on the one hand and by greed on the other, so that very little is accomplished for the genuine financial uplift of the profession. As a matter of fact, every physician does give considerable thought and discussion to money matters; only hypocrites and dreamers think that they do not. Practically every one of us discusses these questions when he meets a friend to whom he can confide his financial problems. These are not discussed publicly because no one wants to appear mercenary and so lose practice, yet in this twentieth century there are few localities where the reputation of being a good financier will seriously lessen one's practice.

There will be found few people who will deny the Government reports that the cost of living has increased upward of 50 per cent within the past two decades. Irving Fisher in his recent work on "Why the dollar is shrinking," has shown this in an unassailable way; and he concludes that there can be no question that the actual cost of buying a given quantity of staple commodities is greater by 50 per cent. than it was eighteen years ago; or, in other words, that the purchasing power of the dollar has been cut in two—the dollar of eighteen years ago is worth 50 cents now. Fisher furthermore points out that the general trend for the next two decades will be upward for the whole world, and that this will be all the more certain and more marked because of the present war. This increased cost of material things is paralleled by the increased cost of labor in practically every walk in life. I have before me the report of the Department of Labor on the result of an inquiry into the union scale of wages and hours of work, as they have prevailed

in the United States since 1840. There has been a steady increase all along the line. Between 1840 and the Civil War wages increased about 10 per cent.; during and after the Civil War they rose another 30 per cent up to 1870; then they remained about stationary until 1896, when they began to rise, and they are now 30 per cent higher than they were in 1896. The present report of the Department of Labor on 93 trades for 1914 as compared with 1913 discloses that in one year 78 trades showed a marked increase in wages over the preceding year, and 15 no change. The highest scale paid at that time, one and a half years ago, was for bricklayers, who received in several cities 87½ cents per hour. In some places painters received 75 cents an hour; freight handlers in New Orleans, 61 cents, and so on. In practically every trade over-time and Sunday work was paid at double rates. Since this report was made, these rates have materially increased. The Bureau of Labor announced recently that 500,000 employees in the State of New York received 4 per cent more wages in October last than in September, and 16 per cent more than a year ago.

Let us, however, take the rates and hours of work of one and a half years ago (as quoted above) of the bricklayer of San Francisco, Cal., or Dallas, Tex., allowing him double pay for over-time work, i.e. more than eight hours per day, and the same for Sunday work. Granting that he works twelve hours per day and seven days per week, he will receive \$400 per month, or approximately \$5,000 per year. I have used as a basis twelve hours a day and seven days a week, because that represents a fair working schedule for the average general practitioner. Many work more than this, but this will afford a fair average. In the case of the bricklayer, we have a mechanic who is paid for his services while he is learning his trade, who does not pay anything for his education, and whose work requires no great skill; yet he receives a compensation far in excess of that of the average physician. From a canvass among men who are intimate with the rank and file of the profession, I have come to the conclusion that the average man's income is not more than \$3,000. To compare the economic relations between the money invested in a medical career, the time and effort spent in study and preparation, and the lean years, with that of the bricklayer would seem at first sight to be a joke. Economically, the bricklayer is immensely better off. In addition, let us compare the cost of the physician's occupation, his clothing, and that of his wife and children, the cost of his office and of his equipment, his medicines, his societies, his vehicle—all these things amounting to at least \$1,000 per year more than that of his bricklayer neighbor—and one finds the condition still more serious. To all this must be added the fact that whereas the bricklayer's price per hour must and will increase as the years go along—it has done so in the past twenty years, and his union will see that it so continues—the physician's rate of pay is but little better than it was thirty years ago. Here and there throughout the country it is better, particularly in the West, but in the main it has, on the other hand, depreciated in the sense that the dollar fee of twenty years ago has now a producing power of less than fifty cents.

I might compare the physician's with other occupations, and the same thing would be found, and this is even so in the other learned professions. Whereas a decade ago a young lawyer would gladly

*Read before the Philadelphia County Medical Society, January 12, 1916.

write a deed for \$3, now he must have \$5, and the same scale of advance applies with other work of the law.

Some time ago I saw an account-book of a physician practicing near Plainfield, N. J., during the Revolutionary War. He was a good book-keeper and he charged from thirty-six to fifty cents for each visit. This seems ridiculously small, but when one compares the purchasing power then and now, it amounts to between \$2 and \$3 of our money.

In the fee table as drafted in 1798—118 years ago—by the State Society of New York, we find the charge for an ordinary visit to be \$1; if with a single dose of medicine, \$1.25; if for a contagious disease, \$5 for first visit and \$3 for succeeding visits. A night visit was \$5 and mileage charged at the rate of \$1 per mile. When medicines were dispensed, the charge was 12 cents per powder or pill, and 12 cents per ounce when liquid mixtures were dispensed. Curing gonorrhea was \$10 to \$20, and syphilis, \$25 to \$100. A tonsillotomy was \$25; an ordinary confinement, \$15 to \$25, and for a difficult case up to \$40.

When one considers that these rates of 118 years ago might well stand in many communities to-day, and that withal the purchasing power of money has made the dollar of that day worth from 30 to 40 cents now, one can easily see that so far as professional fees are concerned we have stood still. The physician should according to that scale receive from \$3 to \$5 per visit.

Again, let us compare the services now rendered to the public by the average physician with those of a generation ago. The long and patient examination, the laboratory work, the office treatment, the rapid answering of calls—all of you know that in our boyhood when a physician was called, one was fortunate if the patient saw him before sundown. Now, your telephone and your auto make it a matter of minutes, yet compensation has not increased. Ours is the only profession that has not capitalized our increased services, and we must do so and do it now or suffer the consequences.

Now, if the cost of living has increased 50 per cent, and if the wages in practically all the other trades and branches of labor have risen while we are standing still, as a profession, we are fast running into bankruptcy. Individually, you will say that this is not so, and as far as the individual members of this audience is concerned it may not be true, because unfortunately the men who most need such advice are not society members, and yet it is for them that we must labor to bring into being a living wage. One says to himself: "I am better off than Dr. So-and-So, who was my preceptor thirty or forty years ago, and he was one whom I then thought to be a successful man; I have more luxuries; I have an auto, where he had an old horse," and so on. So far as his condition of that time was compared with the standard of the present you are doubtless right; but compared with the standard of his friends and equals of that day, most of you will agree that he was economically better off. And yet, compare for a moment the cost of his education with that of yours, and the other expenses, and you will be more forcefully struck by the disproportion between your condition and his from a financial viewpoint.

In discussing this subject, I am going to depart from the old idea that the physician is a poor business man. As I see the present generation, I should say that the genus has changed, that collec-

tions are made and books are more carefully kept, but that altruism is just as prevalent as of old, and this gives us the impression of being very poor business men. Of course, in the long run it is just the same from a financial standpoint. Methinks I hear the note raised, "the practice of medicine is not professed alone for the money one receives." This I grant, and I believe we all get pleasure and fun out of our work; that goes far in compensation, but so does any true laborer—we have no monopoly in this matter—yet we must live and live up to the standards of our time and place, and beyond that of other professions.

This all leads me to the question of the evening: How are we, each and all of us, going to increase our annual income, within the code of ethics? Whether or not the code of ethics will be the rule of morals of the next generation may be questioned by some, inasmuch as what is morally wrong in one generation may be morally right in the next; but I take it that so long as we fly under that flag only discussions in that line should be permitted. There are many ways to raise one's income without the code, but he who runs counter to the moral feelings of his peers in his generation will be ostracized in medicine as in every other walk in life.

In looking for a possible increase in the income of the practitioner our first thought is, How can the fees for our ordinary services be increased? Right here, I may say that the profession is indebted to Rochester, Minn., for many advances in surgical teaching and skill, though these might be evolved in a hundred other cities of the country, but there is one thing which Rochester has taught us more than anything else, and it might well be called the Rochester idea. It is the successful merging of business methods into professional practice. I venture to say that not one surgeon who goes there but comes away determined to place his surgical practice on a firm business foundation, and he generally does so, and medical men who go there try to do the same.

There are many ways by which the physician might considerably increase his total income, such as by better book-keeping, increasing his practice, etc., but these are individual for each physician and do not affect the profession as a whole. To raise the total income of the profession will necessitate the raising of fees along the whole fee table. Any discussion of raising the total income must take into consideration the method of charging as a basis of each service rendered. It is sometimes urged that physicians should charge by the case and not by each visit. This may occasionally work out in the instance of long illnesses, but inasmuch as most patients are seen only once or twice there is no possibility of any such method of charging in all cases, and the vast amount of work would not fit in such an arrangement. It has also been urged that the physician should charge for the time spent on a case, both during the examination and afterward, and that time expended be the basis of all charges. Lawyers do this successfully. The individual nature of the practice of medicine renders this difficult, yet in some instances it works out satisfactorily. Custom and the law have, however, settled on more or less fixed fees for ordinary office counsel and house visits in each community, varying somewhat, but much the same in each medical circle.

For purposes of discussion, we will use the rate of \$1 for office counsel and \$2 for a house visit, for

the ordinary general practitioner. In any case those fees may be increased only (1) by a general and concerted effort on the part of the profession in raising the fee table of the community at one time; or (2) by the individual physician raising his fees independent of his brethren, and thus setting a standard for the community.

The ideal method, of course, is to raise the fees as a whole, so as to approximate a living wage, just as the trades unions do, the living wage to be determined as the result of collective investigation. In certain parts of this country this method of general increase of the fee table has been done successfully. I know of a Pennsylvania city where it was done a few years ago, and no one would want to go back to the old conditions. A few patients were lost by those who banded together to get a living wage, and here and there a doctor backslid, but every physician in that town was much better off financially at the end of the year. All of the practitioners did not join in the movement, but all benefited by it. The result was attained by the formation of a medical union of the practitioners in the neighborhood. The fee table was published in all the local papers and the advertisement was paid for. There was no adverse criticism in the press, because the advertisement was paid for, and seldom is an honest customer scored by the press if he pays well for his advertising. At any rate, the advertisement contained a statement that owing to the high cost of living, the prices of medical services must be raised. After the nine days' wonder, there was no complaint. A special benefit of such a move is that once done a further rise as necessity demands can be much more easily accomplished.

From an extensive experience with medical economic societies, leagues, unions, etc., I have come to the conclusion that in a large city the only mechanism that can successfully bring into being a fee table is the County Society. Other societies of mushroom growth do have much more evanescent energy when they are started, and look promising, but almost invariably they fade away after a year or two. In a small community, conditions are different, and such organizations do persist; but in large cities permanent medical organization is not an easy thing to bring about, and attempts to bring *all* of the members of the profession into one body, even though the aim be for the common good, are but empty dreams. Most of the profession would rather be sacrificed than to find their names bracketed with crooked sticks and doubtful moralists. The impersonal character of the County Society is sufficient guarantee that no individual or group of individuals will thereby feather their own nests or lift themselves into the limelight. In a large city like this, such a plan is not so easily carried out, yet if such an organization as this would deputize a committee to insert articles on this subject in the daily press, paying full advertising rates for the same, and then insert the fee table, even though it cover but a few services, much good would be accomplished. Some will fall by the wayside, but at the end of the year every one will find a material increase in his income.

When this phase of the subject, *i.e.* the comparative high cost of living, is presented to the patient there is very little complaint, as the average layman does not stop to think of this disproportionate increase in the cost of medical life. The subject must be agitated and reagitated in the press, otherwise increased remuneration will be difficult; when such

a thing is done impersonally, there can be no hard feeling. However, until there is some change in the organization of our present societies, the individual practitioner must content himself with raising his fees to a living wage, independently of his brothers. At present some accomplish this by having a sign in the office advising all of the clientele of the new rates. This is done particularly when the practitioner moves into a more exclusive neighborhood or into a new town, or on return from a course of study. In conversation with those who have done this, I have been told that it was successful in their practice. Occasionally a practitioner sends out such a notice to all his clientele. The average man will not do this. The commonest method employed is to provide for a gradual increase in fees, beginning with office service and extending to other services. The office fee may be raised by raising the fee for the first consultation, and allowing later consultations at the old figures. If the former office fee has been \$1.00, then \$2.00 is charged for the first consultation and \$1.00 for each succeeding visit for that particular illness. This may be done for a short period and then gradually all of the office work may be charged at \$2.00 per visit. As every one knows, the vast majority of office patients visit the office only once for one ailment, it soon becomes an easy matter to make the fee uniformly \$2.00. To do this, however, one must give more service to the patient than has hitherto been generally done.

Firstly, a complete examination of each patient should be made at the initial visit. It is rare for any one to complain at the extra charge when he has seen time spent and work done. This is the chief explanation of the existence of the osteopath. A complete examination will pay in another way that is not always recognized, *viz.*, the finding of other defects than are complained of and the treatment of such abnormalities. There is scarcely an adult who is not suffering from some defect which he considers to be of minor importance, and in many instances such diseased conditions can be remedied. If one will always keep this likelihood in mind in making an examination, the sum total of one's revenue at the end of the year will be materially increased.

At subsequent visits either a partial examination with instruments of precision, such as the sphygmomanometer, stethoscope, etc., or some special treatment must be instituted. Simply to tell a patient to keep right on doing as he had been doing will not be willingly paid for at the increased price. He must feel that he is getting the worth of his money, even though he does not pay cash at each visit.

As to special treatment, it means the use of some form of mechanical apparatus, whether it be in the shape of sprays for the nose, throat, bronchi, inhalation, electricity, high frequency x-ray, etc. There is scarcely a disease or complaint that may not be treated by such means, and whatever may be said of their ultimate value they do make the patient feel better at the time, and for this he rarely objects to paying a larger fee than he would for the receipt of the prescription and the advice, the latter part of which may be really the most important to him. Furthermore, it often brings him back to the office, which is not the case when only a slip of paper is handed out to him.

In this matter of increasing our service to the patient our first and foremost aim should be the

increasing of our armamentarium for the relief of symptoms in our office that the patient could not possibly have at his own home. The day when a physician could hope of himself to raise his office fees while his office consists of a chair, a table, and a prescription pad will never come. The investment in such equipment can be made to pay good returns, both as to pleased patients and full purse. Many argue that physicians could not afford to spend the time. Well, if such is the case, that five or ten minutes extra service cannot be rendered to each patient, then these men are happy and prosperous, and need no advice, and will have no trouble in raising their fees whenever they wish to do so.

Many neglect to charge for the minor activities in medicine such as writing certificates. Telephone advice and explanation as to treatment should be charged for at office rates. Charging for such service never causes a loss of patients.

The raising of the fee for house visits is more difficult. However, increased service and the charging for every patient seen in such visits will add materially to the sum total. I mention this because many men neglect to charge for each and every patient seen at a house visit. The increased charge at first may be made for distance, say half a mile from the office and then nearer; or increasing the charge for the initial visit, and so on. For special services the fee can be more easily raised than for general work.

What I have said of the general practitioner applies, but to a lesser degree, to the specialist and the surgeon. The same general principles apply, and both specialists and surgeons must also raise their fees if they wish to progress in their line of work. It has become a custom to criticize surgeons' fees. This is sheer folly. It is like cutting off one's nose to spite one's face. The surgeon must live on a higher plane than the general practitioner; he must have more and longer preparation, do more work for nothing, and be longer and more uncertainly idle. His general fees at present are scarcely sufficient, and the practitioner belittles the value of his own services when he utters such criticism.

Another way of making the patient feel that he is getting more for his money is the habit of dispensing. This is, I understand, a thorn in the minds of some, and I will not discuss it, but I am quite sure that in some communities at least it enables the physician to increase his fees without lessening his clientele. Office practice is cultivated by this means in places where the fee at the office and at the house are the same. The patient feels that it is worth the extra trouble to go to the office by saving the cost of at least some of the medicines. In these days of war this has come to be a very important factor. Nowadays the average prescription costs as much as the office fee. While I do not advocate general dispensing, still the use of a few staples in conjunction with a prescription will undoubtedly add to the ease of securing the extra fee in the office.

The problem of raising the fee table in a neighborhood where the wages have risen recently offers little trouble as a rule. The same holds true in the case where the physician's practice has advanced in financial caste, *i.e.* where his patients are of a wealthier type than he formerly had. With the poor and with those who have stood still, a more troublesome question arises. One may, however, establish the standard, even in such cases, by charg-

ing the advanced fee for one examination and nothing the next; or if the old rate be allowed to them the patients are informed that they are being treated at a special rate. This will make it easier to secure the larger fee from any one who may be referred by those of poorer financial status.

In general, the practitioner hesitates to raise the fee for one of two reasons. Either he fears that the patient will not continue to consult him and that he will in the future go to a brother practitioner who is anxious to work at a lower rate; or because of altruism, *i.e.* because he feels that it would be a hardship to the patient if he takes the extra money.

The first reason will always be a stumbling block unless there be united or nearly united action; yet if one sees at the new rate only one-half the number of patients seen at the rate of the year before, the financial recompense will be the same and much better work will be done, and much better advertisers will be made in the shape of pleased patients, and the way will be prepared for a future remunerative practice. The caste recommended by such practice will grow equally, and will probably be greater than that recommended by those who deserted.

As to the second reason, altruism, we are all apt to think that the patient should make no sacrifice when he comes to consult the physician. We sympathize with him, we pity him on hearing his tale of suffering or his financial or domestic loss—and every patient who comes has one or more of these burdens. We want to lessen all, or at least as many as possible, of his sorrows, and we begin by cutting our own fees, as though we were the almoners of the world. This is an injustice to our families and to ourselves.

The annual budget of every one should contain provision for sickness, to form about five per cent. of his annual income, and this should be considered just as necessary as that for the butcher or baker. If the patient has squandered this on pleasure, luxuries, etc., then there is no reason why we should lose at the end of the rope. When illness comes to a household, no one ever heard of the grocer or butcher cutting his bills in half or lessening them in any manner; the pharmacist makes no change in his rates, nor does the undertaker. Why should we be official sharers in the misery of all mankind? And yet we all do it, have done it, and will do it again. Our ideas and words are just as much our goods for sale as the tea or sugar of the grocer.

If the patient can even at a considerable sacrifice pay the full fee, he should be so charged. Medical or surgical service that is worth while is worth much sacrifice on the part of the patient. Recovery from a severe illness or operation is worth a considerable sacrifice for at least a year thereafter. In the salvage of a ship at sea, forty per cent. of its full value is not considered too much for saving the ship; yet who will pay 40 per cent. of his entire property for saving his life? Ten per cent. of the annual salary is a fair fee for a capital operation, but as yet there is no such basis for medical services. Yet constantly by harping on this question by the profession we will gradually educate the public to pay a more commensurate fee. Some of us have found that the placing of a slip on the office desk, containing the words "Remember Thy Home" has been a good investment when such questions obtrude themselves.

There is not one of us who fails to recognize

genuine distress and treat it cheerfully without recompense, but the dubious cases are too often given the benefit of the doubt. It is in such cases that a nurse or female attendant will sense the financial situation better and more justly than we can. Those practitioners who have the financial part of their practice handled by the office nurse find that there is a material increase in their annual income. The physician living in the dreamland of the past does not want to make the giving of medical advice a business transaction. The patient of to-day, however, is essentially different from the patient of the last century. He views the going to the doctor as a business transaction in practically every instance. He has thought it out in that way, but of course he does not state it in words.

I think that any impartial observer will agree that every one of these discussions does have results; that each one goes away from these meetings determined to improve his business qualifications, just as we go away determined to do better work after listening to a scientific programme where new ideas are evolved or where the old thoughts are dressed in a new gown. Constantly having this matter drummed in one's ears, or having it before the eyes continually begets the backbone to charge a fair fee for one's services and secure a living wage. I am quite sure that books are better kept, bills sent more regularly, and many other matters of office routine better taken care of by the average doctor now than obtained a decade ago. This phase of economic study must in the very nature of things increase yearly, and societies all over the country must do as you are doing here—setting aside one or more nights annually for its study.

220 W. 139TH STREET.

THE BACTERIOLOGY OF THE RECENT GRIP EPIDEMIC.*

BY CHARLES HALPIN NAMMACK, M.D.,
NEW YORK.

ADJUNCT ASSISTANT VISITING PHYSICIAN, BELLEVUE HOSPITAL.
(From the Research Laboratory, Department of Health, City of New York.)

WE are indebted to the French for the term "La Grippe," which is derived from the verb "gripper," meaning to seize, clutch, or nab, and certainly it is a name that is thoroughly appreciated as apt by one of its victims. There has arisen much confusion in the use of the two terms grip and influenza for the most part synonymously. Many insist that influenza is applicable only to the infection that is caused by the organism of Pfeiffer, the influenza bacillus. As a matter of fact, the attacks may be accompanied by one or the combination of several organisms, among which the bacillus of Pfeiffer is frequently found, but in many epidemics in by no means the majority of the cases. Other organisms which may commonly be found are the pneumococcus, the streptococcus, and *Micrococcus catarrhalis*, of which I shall speak in more detail later.

The present epidemic, which I am happy to say seems to be somewhat on the wane, has depended upon three main factors. First, the tremendous variation in climatic conditions which has occurred in the past two months; second, the crowding together of great masses of people in badly ventilated cars, subways, and moving picture and other halls;

*Read before the Brooklyn Society of Internal Medicine, January 28, 1916.

and, third, the contamination of the air which we have been obliged to breathe by the coughing, sneezing, and spitting of those already suffering from some form of respiratory infection, usually of the common cold type. The abrupt transitions which occur in going from crowded overheated indoors to the chill outside air result in an alternating hyperemia and congestion of the mucous membranes of the respiratory passages with a subsequent constriction of the blood vessels which produces a condition of affairs that is very favorable for the reception and subsequent vigorous growth of the infecting organisms, and which may result in the development of the characteristic clinical picture and symptoms of grip.

The campaign which the Department of Health has undertaken under the direction of Dr. Haven Emerson, the Commissioner of Health, and Dr. Bolduan, Director of the Bureau of Public Health Education, has been in the main one of popular education in the prophylaxis of respiratory infections. This has been carried out chiefly through the medium of the lay press and has consisted in instruction in the meaning of "common colds," especially in regard to their infectivity, the dangers of contact with those suffering with colds, and the avoidance on the part of those already victims of all coughing, sneezing, and spitting, except under proper circumstances. This last and most important portion of the work was pushed most vigorously by the distribution of leaflets and posters in the subways and elsewhere, urging people to use the proper precautions in so doing and by the activities of the Police Department in summoning before the city magistrates all persons detected expectorating in public places. This last measure resulted in one week in more than 1,600 arrests and 1,400 or more convictions and fines.

Our work at the Research Laboratories under the direction of Dr. Anna W. Williams has been the determination in a tentative way of the organisms present in the secretions of persons suffering from common colds. Before going into a description of our methods, I should like to say a few words about the influenza bacillus and the work which has been done bacteriologically in the past on the respiratory infections. Searched for repeatedly in epidemics of grip, which had been recognized as a clinical entity for almost a hundred years, it was not until 1892 that R. Pfeiffer discovered the small bacilli in large numbers in the sputum of patients suffering from the tracheitis and bronchitis which frequently occur in its course. Since that time the most voluminous amount of work has been done upon this problem and has resulted in the finding of a great many different organisms in connection with these conditions.

This variation in the finding does not seem to be due to technical errors, but rather to the two facts (1) that people are differently susceptible at different times, and (2) that in different epidemics, various organisms seem to be more virulent and prevalent than certain others.

To illustrate this point: In 1908 Allen reported the bacteriology of an epidemic of colds in London as follows: *B. influenzae* in only 2.4 per cent.; Friedlander's bacillus in 19 per cent. *B. coryzae segmentosus* in 26.6 per cent, and *Micrococcus catarrhalis* in 28.6 per cent. In 1911, Niles and Hastings of Cornell reported a series of cases in which their findings were as follows: *Micrococcus catarrhalis*, 15; streptococcus, 7; pneumococcus, 7.

B. influenzae, 7; and *Micrococcus tetragenus*, 6 per cent. A preliminary report by Dr. George Mather of the present Chicago epidemic is that the predominant organisms have been the hemolyzing streptococcus and pneumococci. These will serve as a basis of comparison with our results and illustrate the tremendous variation in the types of organisms present in which the clinical picture is the same.

The sources of our cultures have been three, laboratory workers, private patients of doctors connected with the department, and nurses, doctors, patients, and employees of the various hospitals, but in particular in Bellevue Hospital. Before taking a case as suitable for study a careful inquiry was made into the history and symptoms, and whenever possible, a physical examination was made. Of the cases accepted for study, that is, those that were clinically grip, the facts noted were occupation, date of onset, character of first symptoms, present symptoms and condition, and in general, the degree of severity, prostration, fever, and complications; also, the history of exposure and of contact with other cases of respiratory diseases. We consider this last as being the most important of all because it furnishes us with authentic information as to transmission by contact which we regard as the essential etiological factor in the present epidemic.

In collecting our material we used two methods of procedure. Method I is used in cases whose local symptoms are chiefly nasopharyngeal with little or no cough or expectoration. A sterile cotton swab on a stick is passed well back into the posterior nares from the front and revolved several times. It is then withdrawn and a direct smear is made upon a glass slide. Another swab is then introduced and the material so collected is ground thoroughly into a tube containing 1 c.c. of beef bouillon to which a little blood has been added. Method II is employed in cases which present cough and expectoration. The patient is instructed to expectorate into a sterile glass bottle a portion of sputum which he gets up only with a deep cough. These sputum specimens should be as clean as possible and desirable specimens are not difficult to obtain from patients of intelligence when their purpose has been explained. Washing the mouth out with saline or a mild antiseptic according to the method of Kitasato lessens the possibility of contaminations from the mouth, but we have not found it essential to the obtaining of satisfactory specimens.

The specimens must reach the laboratory within 24 hours of their being obtained. Here, the further procedure with the blood bouillon culture and the sputum is the same. The direct smears are stained by the Gram method and are examined to determine the morphologic types and the comparative predominance of the organisms present. As the presence of hemoglobin is necessary to the life growth of *B. influenzae*, the specimens are plated upon veal-agar plates by the blood drop method. A drop of horse blood and a drop of the material are placed upon the plate, gently mixed, making four dilutions, and then streaked across its surface. The swab is also streaked across the plate.

The influenza bacillus is easily recognized upon the plates by the delicate, discrete, whitish areas in the mass of blood and is further identified by fishing, smears, and staining. It has not been deemed necessary in this work to prove its hemoglobinophilic property further.

The balance of the material is employed in Part II of our process of identification, to wit, the isolation of the pneumococci and streptococci, if any be present. As you no doubt know, the work of Cole, Avery, Dochez, and others at the Rockefeller Institute has shown that there are certain forms of pneumococci that are virulent for human beings which are also very virulent for white mice.

One c.c. of the material is injected into the peritoneum of such a mouse. Six hours later, if pneumococci are present the mouse is dead. Autopsy reveals a suppurative peritonitis. The suppurative fluid is washed out of the abdominal cavity with sterile saline solution and if the culture be uncontaminated we now have a saline suspension of pneumococci ready for further identification. In addition, the peritoneal fluid and the heart's blood of the dead mouse are plated out, as is sometimes necessary to obtain a pure culture.

I shall not attempt to discuss the division of the pneumococci into groups as it would bring up too many points of purely technical interest. Suffice it to say that Groups I and II are agglutinated by the experimental sera derived from immunized horses. Group III, which is the *Pneumococcus mucosus capsulatus*, is recognized by its peculiar slimy growth, and Group IV is an atypical group of all the pneumococci that kill mice, but do not agglutinate or grow in the characteristic manner of Group III. It is of interest to us only that pneumococci were found in a great many of the cases that we studied and that with but three exceptions they belong to Group IV, the miscellaneous group, which in cases of frank pneumonia gives a mortality of only 10 per cent. as compared to the 30 per cent. mortality of Groups I and II and the mortality of Group III, which has been given as 40 per cent.

The number of cases we have studied of this epidemic has been about fifty, and nineteen have shown influenza-like bacilli, but sometimes in so small numbers as not to be considered of etiological importance. The influenza bacillus was found alone in six cases and associated with some other organism in thirteen cases. The pneumococcus was isolated in eighteen cases. Other organisms found were the hemolytic streptococcus six, Friedlander's bacillus three, staphylococcus in three, and *Micrococcus catarrhalis* in only one.

I want to emphasize especially the fact that even after the severe symptoms have subsided, the patient who has suffered from an attack of grippe may remain to the community a source of danger, not as serious perhaps as a typhoid carrier, but none the less requiring such local treatment as will result in the destruction of the residual infection. To illustrate this I shall cite two cases.

CASE I.—Dr. D., interne at Bellevue Hospital; exposed in the course of his duties to both gripes and pneumonias. He was taken ill rather abruptly with the characteristic symptoms. His temperature at the onset rose to 103°. The course of his illness was one of moderate severity and prostration, lasting about two weeks and subsiding with moderate bronchitis and expectoration. Sputum culture taken at the height of the infection yielded a pure culture of *Pneumococcus mucosus capsulatus*. One month after his attack, he developed the symptoms of a sub-acute double frontal sinusitis. A swab and blood bouillon culture taken in the manner already described yielded a *Pneumococcus capsulatus*.

CASE II.—Dr. A., laboratory worker; no history of exposure or contact. Usual grippal attack beginning with rhinitis and running a fairly brief course of moderate severity. Following subsidence of attack which

occurred around Christmas and ever since nasopharyngeal cultures have been taken and always proved to be *Bacillus influenzae* in pure culture.

Both of these cases were undoubtedly a source of danger to those with whom they came in contact and from a clinical standpoint the nasal cultures proved of distinct advantage in directing treatment to be employed locally for the protection of others as well as aimed to prevent the development of subacute or chronic infection or complications.

To summarize: (1) Grippe and influenza should not be used synonymously, but the latter term should be restricted to cases in which the influenza bacillus is present. (2) The aim of the Health Department of New York in combating the present epidemic has been to instruct the people in the dangers of colds and how to avoid them. (3) The organisms present in the secretions of patients suffering from grip have been determined by means of sputum and nasal cultures. (4) Most of the cases were seen when fully developed or declining and the presence of the organisms found is strong presumptive evidence that they are etiological agents, but we have not absolutely proven this relationship. (5) The influenza bacillus was seldom found alone, but was found frequently in association with other organisms. Pneumococci and streptococci were present in many cases. (6) The epidemic is spread by contact and many persons are undoubtedly carriers of organisms that may cause grip.

HEALTH INSURANCE AND THE PREVENTION OF TUBERCULOSIS.

By JOHN B. ANDREWS, PH.D.,

NEW YORK

SECRETARY, AMERICAN ASSOCIATION FOR LABOR LEGISLATION.

To Dr. Frederick L. Hoffman we owe a special debt of gratitude, for he has been one of the men most active in this country in pointing out the occupational aspects of tuberculosis. Largely through his researches the interested public now knows that the incidence of tuberculosis varies among the dusty trades according to the nature of the dust and the degree to which the workers are exposed. On this account tuberculosis may be classified as an *industrial* disease.

Hardly less energetic has Dr. Hoffman been in pointing out that tuberculosis is a *preventable* disease. In 1908 he estimated that it would be wholly possible to reduce the then existing death rate from tuberculosis among wage-earners by 37 per cent. This he calculated would result in an annual saving of 29,000 lives in this country. He concluded this earlier address by saying: "With such results clearly within the reach of practical attainment, nothing within reason should be left undone, as a national, State, and individual, or social duty to prevent that needless, but now enormous, loss of human life from consumption in American industry."

To-day we are presenting a wholly practicable and reasonable method of prevention, one that is new and as yet untried in this country, although it has been tested and found effective by European nations. This new method is compulsory health insurance for all wage-earners, insurance to which employers, workmen, and the State contribute. Although this may at first seem radical, such a

measure is justified, for tuberculosis is too often an industrial disease for which the employer is largely responsible—responsible to such a degree that compensation has already been paid in Massachusetts. Progressive employers have already begun to meet their responsibility by installing sickness insurance systems for the benefit of their own employees. The community is also responsible for diseases primarily due to defective housing and sanitation, and does its utmost to prevent such diseases. The workman is often responsible for his own illness, and sometimes unites with his shop mates to provide treatment, but is frequently unable to afford the necessary expensive medical care. The proposed distribution of the contributions thus recognizes the responsibility of all, and, by dividing the cost, helps the community, the employer, and the workman each to bear a proper share of the burden.

One of the most important fields of activity of the American Association for Labor Legislation has been social insurance. Through active campaigns it has aided the progress of workmen's compensation for accidents until now thirty-three of the States and territories have this legislation. This association also took the leading part in stimulating investigation of the strictly occupational diseases which are also now compensated in a few States, but it is recognized that for the whole problem of sickness among workingmen such provision is insufficient. In December, 1912, this Association, therefore, provided for a national committee to concentrate on insurance against sickness. As the result of three years' work a bill is now drafted according to standards adopted and distributed for criticism and suggestions more than one year earlier.

The plan combines the best points of the British and the German systems. Under this plan employers and workers would pay into a fund, while the workman is well, equal contributions, the joint sum of which the State would increase by one-quarter. The contributions, we think, should be graded according to the wages of the workman, and the total contribution of employer and workman should be higher in those industries or in those particular plants in which the sickness is greater than the average. In return for the combined contributions the worker would receive medical care, including medicines and nursing, a cash benefit for a maximum of twenty-six weeks in a year, and there would be funeral benefit at his death. The American employer would benefit by the increased efficiency of the workmen, just as the German employers admit they have gained. It is desirable that the insurance should be conducted through self-governing associations organized along trade or local lines so that the amount of sickness in a trade or in a particular locality may be brought to the attention of employers and workmen. This organization would lend itself very readily to an effective health campaign. As a result the community as a whole would gain by the increased healthiness and by the diminution of poverty manufactured by sickness. Moreover, State supervision of the associations is desirable in order to insure solvency and to guarantee that contributions are not unnecessarily high and benefits not unduly low.

The preventive aspects of such a measure are not difficult to discern. Under the impetus of

workmen's compensation there has been a growing movement for "safety first" and for physical examination of employees. The object of the first is to reduce *accidents*. That of the second is to improve the workman's health, thereby increasing his efficiency and diminishing the likelihood of prolonged and expensive convalescence following an injury. A comparable movement under health insurance to reduce *sickness* and its cost, may confidently be expected. The associations of employers and employees which pay out benefits would have a financial inducement to prevent sickness, in as much as prevention would result in a saving of expense. Therefore it is quite within the bounds of probability that the associations would find it to their financial advantage to urge early treatment, and even to provide the necessary hospitals and convalescent homes in order to expedite recovery. Not only the health of the workmen, but the sanitation of the factory—heating, ventilation, lighting, noise, and even the mode of cleaning—would all receive attention, since an improvement in these disease-provoking factors would avert much illness and thus reduce the premium payment.

Moreover, improved facility for medical care would be a preventive measure in itself. Many workmen who at present are unable to afford a doctor's care until it becomes imperative, would then be able to consult a physician as soon as it was clear that something was wrong. This should result in the detection of disease while it is in its incipient stage and more amenable to treatment. Thus after three years' experience with compulsory health insurance, the British physicians confess that only since the passage of the insurance act have they been able to treat anemia among the working classes.

These preventive measures are not Utopian dreams, but have been actually realized in foreign systems of health insurance. Although these preventive aspects are not confined to tuberculosis, the actual work done in promoting an effective fight against tuberculosis and in diminishing its ravages stand out, perhaps, more clearly than in the case of almost any other disease. Thus in Great Britain the provision under the national insurance act of 1911 for treatment for insured workers has stimulated a powerful national crusade against the disease. The committee which was appointed to consider the hospital accommodations necessary to provide insured tuberculous workers with treatment in sanatoria or otherwise came to the conclusion that the campaign would be more effective if the treatment might be extended to the entire tuberculous population. Later the government announced that it would meet half the expense incurred by local authorities in treating tuberculosis among the non-insured population. Within two years after the act came into operation 115 county and county borough councils in England had submitted plans for the treatment of the entire population, while only eleven had failed to make such a plan.

This really national campaign in Great Britain derived its impetus from the provisions for the insured under the insurance act, and the uninsured too have, of course, benefited. The first effect has been to increase the availability of hospital beds already in existence but previously inaccessible to workingmen; the second has been to increase the actual accommodations. Within

two years after the initiation of the act in England there were 3,000 beds in process of construction, 150 tuberculosis officers had been appointed, 150 new tuberculosis dispensaries had been opened, and nearly 1,000 shelters for out-of-door sleeping had become available. During the initial eighteen months, 19,400 insured tuberculous persons were treated at home, 8,800 through dispensaries, and 19,900 in institutions, making a total of 48,000 insured tuberculous persons who received treatment. Unfortunately, the figures for the non-insured are not available. Although in time this increased provision will result in improved health and lowered death rate, the act has, of course, been in operation too short a time for any statistical effect to be manifest.

In Germany, however, where similar measures have been in operation twenty-five to thirty years, marked results have been achieved. There the invalidity funds which afford benefit in case of prolonged disability are empowered to prevent the impending invalidity of an insured person by requiring the member to undergo treatment. In addition the funds may promote general measures for the prevention of invalidity or for the improvement of the general health conditions of the population subject to insurance. Under the provisions of the law, generous accommodations have been provided, so that, in 1910, 47,000 insured persons were cared for in sanatoria for an average of seventy-three days. In addition to the actual care of disease undertaken by the funds, they have been active in a campaign of prevention, in part through health lectures and in part through the promotion of improved housing. Because of the causal relation between housing and sickness, the invalidity funds have invested large sums in improved housing schemes, until they have become the most important organization in the German Empire for furnishing cheap capital for better homes for the workingmen. The place of insurance in the struggle against tuberculosis is illustrated by the fact that during the years 1897-1910, inclusive, out of a total of 733,000 persons receiving systematic courses of treatment under the invalidity insurance funds, nearly 322,000, or about 44 per cent., were treated for pulmonary tuberculosis.

The explanation of this active campaign against tuberculosis is a financial one. According to investigations carried on between 1896 and 1899 tuberculosis holds third place as the primary cause of invalidity among adult German males. In this sense invalidity means a definite reduction in earning capacity. In 1909 the expenditure of the funds upon tuberculosis was 67 per cent. of the total amount spent upon the care and treatment of all diseases. Under such an insurance scheme it is evidently a "paying proposition" to reduce tuberculosis.

The result of these preventive and curative methods has been a marked increase in the number of cures. In 1897, 68 per cent. were so far cured at the end of their treatment that no danger was felt of their becoming unable to earn their livelihood; this percentage steadily increased until in 1909 it had reached 83. The tuberculosis death rate has decreased from 34.4 per 10,000 in 1880 to 16.6 per 10,000 in 1909, and to 13.65 per 10,000 in 1913.

These figures are sufficient to show that the campaign has been efficient. In the opinion of

leading German authorities this amount of prevention would have been impossible without the industrial insurance laws. Privy Councillor Bielefeldt, Director of the Pension Board for the Hansa cities, says, "The conviction may be expressed, after the experience of several years, that an effective battle against consumption among the working classes would have been all but impossible without the workmen's insurance of the German Empire. . . . Professor Kayserling and Professor Frankel, who rank among the highest German authorities upon the subject, frankly attribute the progress which has been made in the crusade against tuberculosis more to the Industrial Insurance Laws than to any other cause, owing to the fact that these laws have placed within the reach of the working classes resources of healing never dreamt of before."

If increased interest in tuberculosis can be aroused by a measure for health insurance, if through this agency Germany has waged one of the most effective battles against tuberculosis which the world has ever seen, is it not time to try what such a measure will do in this country? Evidence is accumulating to show that representative and intelligent interest in such a plan is rapidly developing in America. Dr. Arthur Bevan as chairman of the Council on Medical Education of the American Medical Association said to that leading organization of medical men: "We are every day coming nearer the time when in this country we shall see laws enacted to provide, by some State insurance scheme, medical care for the poor as has been done for some years in Germany and as has recently been done in England. If the profession in this country is far-sighted it will recognize these coming events and direct them wisely."

An active committee for this purpose has more recently been appointed by the American Medical Association. Mr. F. C. Schwedtman, while chairman of the Committee for Accident Prevention and Workmen's Compensation of the National Association of Manufacturers, in a report to the President and the Board of Directors of that conservative body in 1914 declared: "I give it as my opinion that sickness insurance of some kind, with compulsory contribution on the part of the employers, will be enacted into law by many States of the Union within the next five years and that now is the time to go into this subject thoroughly." The *Union Labor Bulletin* makes this editorial observation: "Judging from the success attending its efforts in securing enactment of accident compensation laws in various States, the American Association for Labor Legislation is the proper body to propose and carry on to fruition plans for sickness insurance. . . . Labor representatives and organizations will lend every aid to such a campaign, understanding best of all, because of individual and collective experience, the economic loss to the nation because of sickness."

In the belief that sickness insurance is the most potent means for preventing illness, and especially tuberculosis, the American Association for Labor Legislation invites thoughtful study and active support of the bill for health insurance which it has framed after consultation with representative employers and workmen and members of the medical profession.

Medicolegal Notes.

Malpractice—Wrong Diagnosis.—Action was brought against a physician for malpractice in wrongfully diagnosing the plaintiff's trouble as cystic tumors, instead of pregnancy. The jury rendered a verdict for the plaintiff for \$500. The judgment of the lower court was affirmed on appeal. "In the present case," the court said, "appellant and another physician positively determined that the patient was afflicted with tumors. Another physician had previously positively determined that she was pregnant, of which diagnosis appellant was informed, according to respondents' case. After appellant's diagnosis, the first physician and another physician consulting with him again examined the patient and determined that she was pregnant, and that she had no tumors, of which diagnosis, according to respondent's case, appellant was also informed. His response to this was that 'the other doctors were crazy.' It may well be conceded that the statements made by the patient to appellant were deceptive, and calculated to deceive. She did not believe at the time of any of her examinations by any of the doctors that she was pregnant. Her first 'suspicion,' according to her own statement, that she was pregnant, occurred three weeks after the operation, when she first felt motion of a quick fetus. Prior to the operation she had menstruation, of which she no doubt informed the doctors who examined her. The expert testimony of both parties at the trial showed that the bimanual test may give indicative results during the fourth, fifth, and sixth months; the same sensation may possibly result to the palpation of the physician's hands from tumors; the same symmetrical development of the uterus may appear from the existence of a tumor; the mother feels quickening before an examiner can feel ballottement or rebound; there is often ballottement upon one examination during the fourth, fifth, or sixth month, and none at other examinations about the same time. So that it is manifest that there might be utterly different, though thoroughly honest, opinions reached by physicians as to the patient's condition at or about the time of the examinations by these various doctors. Appellant's diagnosis proved to be wrong, and those of other physicians correct."

"But did appellant exercise the proper care and diligence in advising, immediately upon his diagnosis, an operation for tumors? There is no complaint made of the operation itself, as to the manner of its being performed. The matter of the ethics and propriety of appellant's conduct in proceeding with the operation without notifying the patient's former attending physician is immaterial. But the matter of appellant's notice that other competent and reputable physicians had positively declared that the woman was pregnant is serious. Surely it put upon appellant a greater degree of diligence and care to be as certain as circumstances and conditions surrounding the case would admit of. Notwithstanding what she may have stated to the examining physicians, pregnancy is not an impossible or improbable condition to the ordinary married woman of the age of 37 years. Appellant urges, however, that the incision made was in the nature of an exploratory operation, to determine the true condition of his patient. As to this, though no point was made of it, he had not the consent of the patient and her husband to make an exploratory operation. Their consent to operate was upon a positive assurance that tumors existed and that an immediate operation was necessary to remove tumors. The appellant having notice of a directly different diagnosis from his, the patient being a married woman of 37 years, living with her husband, not being past her climacteric period, it would seem he should not have hastily flouted the opinion of other reputable physicians that she was pregnant, but might have waited for a time, watching developments, making other examinations, and proceeding with considerable deliberation, unless the presence of tumors becoming more symptomatic, or injurious, rendered the operation therefor more imperative. At all events, it would seem that whether appellant did, under the circumstances and conditions shown to exist, proceed with due and ordinary care in treating the patient, was a question of fact for the jury. The further questions of the damages for any unnecessary pain and suffering produced, as well as financial loss to both respondents, were also questions for the jury. We cannot say that the award of \$500 was excessive."—*Just v. Littlefield*, Washington Supreme Court, 151 Pac. 780.

THE EMETINE TREATMENT OF DYS- ENTERY.

THE rôle of intestinal amebas in the causation of tropical dysentery has long been recognized. Sir Ronald Ross, writing in the *Lancet*, Jan. 1, 1916, states that it was chiefly the work of Kartulis in Alexandria which first definitely incriminated intestinal amebas as pathogenic organism, but he appears to have overlooked the result of the investigations of Lambl and Lösch. In the article on dysentery, in the "Twentieth Century Practice of Medicine," Azevedo Sodré states that Lambl was the first to draw attention to the presence of amebas in the contents of the intestine; he observed them in 1859, in Prague, in the stools of a child affected with dysentery. Other observers had also detected amebas in the intestine, but the nature of the parasite and the rôle it plays as an etiological factor of dysentery were not determined until 1875, when Lösch of St. Petersburg verified its presence in the dejections of a young peasant affected with chronic dysentery. The observations and investigations of Lösch were carefully made, and his description of the parasite, to which he gave the name *Ameba coli*, was so good that very little has been added to it since. The work of Kartulis was not commenced until about 1880 and was already progressing when Koch visited Alexandria in 1883. The previous studies of Lewis and Cunningham had led these workers to think that these organisms were merely pseudoparasites in man. As the result of Ross' own studies, both on amebas and on the intestinal flagellates, he felt almost convinced that all these organisms are, or at least may be, injurious to the host. It appears to him to be a very rash statement to make that any parasite is quite innocuous.

Col. Patrick Hehir and Ross certainly recognized both amebas and flagellates in India in cases of dysentery and diarrhea in 1896; so that Sir Leonard Rogers is scarcely justified in claiming that he first discovered amebic dysentery in 1901, although Rogers can well afford to lose this small distinction in comparison with the immense distinction he has deservedly attained for the elaboration of the treatment of dysentery by emetine. Of course ipecacuanha has been successfully employed in the treatment of dysentery for longer than 200 years, but emetine was not separated from ipecacuanha until 1817, and according to Ross was first recommended for dysentery by Bardsley of Man-

chester in 1829, while Tull Walsh gave it by the mouth in 1891. But it was the careful studies of Rogers which first established the use of hydrochloride of emetine in 1912. Ross believes that while it is not essentially superior to ipecacuanha powder, the hypodermic injection of it is much less troublesome to the patient. He believes that the hypodermic use brings the drug more directly into contact with the amebas at the bottom of the ulcers, while ipecacuanha attacks the organisms on the surface of the mucous membrane and in the lumen of the intestines; he is therefore inclined to favor the use of both at the proper stages in the treatment.

As for bacillary dysentery, according to many authorities ipecacuanha and emetine are useless in its treatment, and Ross favorably refers to the employment of the sulphates of magnesium and sodium, apparently originated for dysentery by the French physicians in the middle of the last century. Consequently it is held by many that we possess specifics against both forms of the disease.

Referring to the treatment with emetine of amebic dysentery which occurred among the British troops in the Mediterranean and the near East, the writer says that as a general rule daily doses of one grain of the hydrochloride were given either in one subcutaneous injection or in two doses per os, morning and evening. As to the continued employment of emetine, as is done frequently in India, opinions of physicians treating the British troops were divided. Some deaths occurred, and suspicion was aroused that these might have been due to the cumulative action of emetine. Indian officers were not inclined to admit that emetine is at all cumulative or mischievous in its effects, but nevertheless practice gradually crystallized into the formula that, unless there was very strong reason for continuing emetine, it should be remitted, at least for a time, after about ten days, especially if it had ceased to do good. And, on the whole, Ross thinks that this is the best practice in acute dysentery. H. B. Dale, writing in the *British Medical Journal*, Dec. 18, 1915, corroborates these views, but he adds that experiments made by him would seem to prove that emetine can produce cumulative poisoning of serious importance.

TREATMENT OF SEPTIC WOUNDS IN WAR.

THE treatment of septic wounds in war is, of course, a question of supreme importance and has been a matter of somewhat heated debate ever since the present struggle began. While it has been demonstrated plainly that aseptic surgery cannot cope with the conditions presented by war under its most modern aspects, it has been also shown that antiseptics in the treatment of wounds in war have their distinct limitations. Opinions, however, differ widely as to the value of antiseptics in wound treatment. When two so distinguished authorities as Alexis Carrel and Sir Almroth Wright diametrically differ on this point, it is difficult to express decided views. It should, however, be borne in mind that Lister taught that the antiseptic treatment of wounds was of more prophylactic than therapeutic value. Strong antiseptics, while they

may destroy the infective organisms, at the same time destroy healthy tissue. Moreover, their germicidal action is greatly reduced in the presence of blood serum. E. A. Morison and W. I. Tulloch in the *British Journal of Surgery*, October, 1915, lay stress on the fact that the use of antiseptics is limited to recent cases, in which infection has not spread into the surrounding tissues; and the application of powerful chemicals that will destroy infective organisms has proved to be efficacious in these circumstances. On the other hand, those wounds which are badly infected before they come into the surgeon's hands are not amenable to treatment by antiseptics, indeed antiseptics do more harm than good. Owing to this limitation of the field of antiseptic treatment of wounds, other plans have been introduced and Wright has come forward as the high priest of the osmotic method.

Morison, before the war, in cases of accidents in civil life, had been employing with much advantage a saturated solution of magnesium sulphate. He has employed the same mode of treatment in English and French war hospitals and the results therefrom, he says, have exceeded his most sanguine expectations. From the bacteriological standpoint Tulloch confirms Morison's findings.

The conclusions reached clinically and bacteriologically by these observers are as follows: (1) Magnesium sulphate by virtue of its being absorbed with difficulty has certain advantages over other salts used for cleaning wounds by osmosis. (2) It also appears to have the desirable property of interfering with the digestive activities of pus. (3) It inhibits to some extent the growth of certain bacteria commonly found infecting wounds.

Asepsis cannot be carried out properly at the front for obvious reasons. Antiseptic measures are not applicable to all cases of wounds, as they have their limitations, although possibly these limitations are not so narrow as many seem inclined to insist. For example, in the treatment of certain superficial wounds it has been shown in the present war that a solution of peroxide of hydrogen is generally efficacious. It clears the wound of pus, is an antiseptic, but does not harm healthy tissues. However, when employing a solution of peroxide of hydrogen a pure and stable solution should be procured. In particular, its stability is of the utmost consequence, for it stands to reason that a solution which will not keep is absolutely of no use. Various other antiseptics, especially Dakin's solution, according to many authorities have proved their worth in the treatment of wounds so that it is not quite reasonable to pooh-pooh the efficacy of antiseptics entirely. The osmotic method has its adherents and the antiseptic method has as many, if not more adherents, and until the question is definitely settled, as it may be ere the war is over, it would be foolish to make dogmatic assertions regarding the relative utility of any one method.

TEN COMMANDMENTS IN MILITARY SURGERY OF THE EYE.

THESE commandments, or counsels, as promulgated by von Grosz in a recent number (November 16) of the *Muenchener medizinische Wochenschrift*

comprise the protective first aid dressing of the injured eye, to be changed within 24 to 48 hours; the cleansing of the eyelids with 3 per cent. boric acid solution; the application of atropine to dilate the pupil (save when intraocular tension is increased in which case 2 per cent. pilocarpine solution should be substituted); the use of the x-ray and sideroscope when there are symptoms of a foreign body (small entrance-wound, intraocular hemorrhage, traumatic cataract); removal of iron fragments promptly with a magnet, and fragments of other kinds by operation; removal of all remnants of eyes without light perception in the interest of the other eye, and the same course in traumatic iridocyclitis without light perception; preservation, in all extirpations, of the conjunctiva and eye-muscles as indispensable in the successful use of an artificial eye; removal of all fragments of projectile in the orbit; repair as soon as possible of all lid defects and ectropions; protection of the other eye in purulent conjunctivitis, which is always infectious.

CURE OF PRIMARY SYPHILIS BY EXCISION OF CHANCRE.

IN former times radical cures of syphilis were often claimed as a result of prompt excision of the primary lesion. The most famous teachers, however, while not denying that an occasional cure might occur, strongly condemned the operation as a routine measure. At the present time excision is doubtless regarded as indicated when practicable and when salvarsan is refused, because the chancre is to be regarded as a focus of infection. At a recent session of the K. K. Gesellschaft für Aerzte, Vienna (*Muenchener medizinische Wochenschrift*, December 21), Scherber reports the case of a man who, in 1904, contracted syphilis and his chancre was promptly excised at Finger's clinic. No secondary symptoms had ever developed. The spirochete had been found in the excised chancre. In 1909, 1911, and 1913 the blood was tested and the Wassermann reaction was found negative. At the time the case was reported the patient had a new sclerosis on the prepuce near the scar of the old one. It contained spirochetes, and the Wassermann reaction was not yet positive. The case was certainly one of reinfection following cure. The author had excised chancres in about twenty cases but could never obtain more than a retardation of the secondary stage. He doubted whether early intensive treatment could produce such a good result as mere excision accomplished in this particular case.

SEPSIS FROM ANGINA.

IT has long been apparent to pathologists that much of the angina which was regarded as a prodrome or early symptom of acute infectious diseases must have represented an initial lesion, with the fauces as the port of entry of the virus—whether bacterium or toxin, or both. In the simplest scarlet fever the angina is a true exanthem, but the streptococcus sore throat, nominally a secondary manifestation, really represents a primary lesion, and is followed by a septic state and metastases, differing in no wise from one which develops *de novo*. We know that many an apparently trivial tonsillitis may be followed by rheumatism, or at least a rheumatoid state, with

metastases to the heart, kidneys, appendix, joints, etc. The angina which often ushers in cerebrospinal meningitis may be an exanthem or a primary lesion. The conservative medical man, however, will continue to believe that the vast majority of anginas in acute infectious diseases are not primary states until evidence begins to multiply to the contrary. Last summer, at the Basle Medical Society, Fahm reported five cases of sepsis of anginous origin (*Deutsche medizinische Wochenschrift*, September 30). Two patients developed fatal peritonitis, two others suffered chiefly from metastatic arthritis, and the fifth case was one of metastatic multiple abscesses.

News of the Week.

City Death Rate.—The Department of Health announces that during the week ending February 12 the number of deaths in New York City was 1,626, giving a death rate of 15.18 per 1,000, as compared with 1,546 deaths and a rate of 14.79 per 1,000 for the corresponding week of last year. The deaths from influenza and pneumonia during the week numbered 346, as compared with 360 during the week ending February 5, and 424 during that ending January 29. The deaths from heart disease and nephritis showed a slight decrease as compared with the previous week, but a very marked decrease as compared with the last week of January. The deaths from infectious diseases during the week were 51, exactly the same number as were reported from these causes during the corresponding week last year. During the first seven weeks of 1916 the death rate was 16.28, as compared with 14.78 for the corresponding period of last year.

Procedure in Diphtheria.—Certain studies recently made by the Department of Health of New York City having shown that in a number of instances patients convalescent from diphtheria who have been released from quarantine after two consecutive negative cultures have, as a result of still later cultures, shown the persistence of diphtheria bacilli in their throats, the department has decided to establish a definite period of quarantine, and announces the following rules:

1. On and after February 28, 1916, no culture will be examined for release from quarantine which is made earlier than twelve days from the date of report of the disease.

2. Two consecutive negative cultures, made twenty-four hours apart, preferably from both nose and throat, will be required as at present.

Fire in the Office of the "Medical Record."—A fire, resulting probably from crossed wires, occurred on Monday night in the publishing house of William Wood & Company. The principal damage was from water.

United States Census.—The Census Bureau reports that it is estimated that the population of the United States on January 1 reached a total of 101,208,315, and that by July 1, 1916, it will amount to 102,017,312. According to the 1910 census, the population of the United States was 91,972,266. The estimated population of New York State, according to the bureau, on July 1, 1915, was 10,086,568; on January 1, 1916, was 10,179,971, and on July 1, 1916, will be 12,273,375. The population of the State, according to the 1910 census, was 9,113,614.

Harvey Lecture.—The seventh lecture of the present series will be given at the New York Acad-

emy of Medicine on Saturday evening, February 26, by Prof. Warfield T. Longcope of Columbia University. The subject will be, "The Susceptibility of Man to Foreign Proteins."

Federation of State Medical Boards.—At the annual meeting of the Federation of State Medical Boards held in Chicago this month, the following officers were elected: *President*, Dr. David A. Strickler, secretary of the Colorado State Board of Medical Examiners; *Vice-President*, Dr. Walter P. Bowers, secretary of the Massachusetts Board of Registration in Medicine; *Secretary-Treasurer*, Dr. Walter L. Bierring, president of the Iowa State Board of Health and Medical Examiners.

Census of the Sick.—The New York City Department of Health on February 19, sent two hundred of its nurses into the East Side to take a mid-winter sickness census. The district covered was the square mile bounded by Pike, Division, Clinton, and South Streets, and the nurses were instructed to note the age, occupation, and sex of each person found ill, the economic conditions under which each lived, and other facts, such as the number of persons living in the room, the type of dwelling, etc. Although a sufficient force to extend the census over the entire city is not available, it is planned to make further investigations of the amount of sickness in other typical districts.

Base Hospitals in New York.—The American Red Cross, with the co-operation of Bellevue, the New York Hospital, and the Presbyterian Hospital, will shortly establish three base hospitals in New York City. A unit, consisting of the doctor in charge, nineteen other physicians, forty-six nurses, and about a hundred lay helpers, will be formed in each hospital and equipped as rapidly as funds become available. Each unit will then hold itself in readiness to leave for any point in the world at the order of Colonel Kean, director-general of medical relief in the American Red Cross. A gift from Mrs. E. H. Harriman of \$24,000 has made possible the immediate equipment of one unit, and a campaign will be at once begun by the New York Red Cross to obtain the \$48,000 necessary for the equipment of the other two units.

French Hospital Train.—The gift to the French Government by two Americans, of a hospital train capable of transporting two hundred and twenty-five wounded soldiers, was recently announced, and on February 14 the ceremony of presentation was held at La Chapelle Station, Paris. For the present the train, which will be under the charge of two surgeons from the American Ambulance, Paris, will be used to carry wounded soldiers from the front to the South of France.

Hospital Ward Dedicated.—Dedication exercises of the Emily Blackwell ward in the New York Infirmary for Women and Children were held on February 19, and at the same time presentation was made of the Emily Blackwell memorial tablet. Dr. Josephine Walter presided at the exercises, and addresses were made by Dr. Stephen Smith and Dr. Elizabeth Cushier. Dr. Smith, who was a classmate of Dr. Elizabeth Blackwell, sister of Emily Blackwell, and is ninety-three years of age, regaled the audience with anecdotes of his early career.

Charitable Bequests.—By the will of the late Louisa W. Anshutz of Philadelphia, bequests of \$5,000 each are made to the Pennsylvania Hospital for the endowment of a free bed, and to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases for the surgical ward.

Industrial Hygiene.—A meeting called to discuss the question of industrial hygiene was held at Cooper Union, New York, last week, and was attended by a large number of persons. The work of the recently created Division of Industrial Hygiene of the Department of Labor was explained by Dr. Louis T. Harris, the chief, and among the other speakers were Dr. S. S. Goldwater, formerly Health Commissioner of New York City, and Mr. Roy Meeker, Commissioner of the Bureau of Labor Statistics, who favored the system of compulsory health insurance.

Personals.—Dr. JOHN T. BLACK, who, because of his appointment as secretary of the Connecticut State Board of Health, has resigned as a member of the staff of the Memorial Hospital, New London, was given a dinner by his associates on the staff, on February 8, and was presented with a gold watch.

Dr. EDWIN C. CHIPMAN has been appointed health officer of New London, Conn., at a salary of \$2,000 a year.

Dr. LOUIS M. GOMPERTZ has been elected president of the Board of Health of New Haven, Conn., succeeding Dr. Charles J. Bartlett, who had refused to serve for another term.

National Leper Colony.—A hearing on the bill providing for the establishment of a Federal asylum for lepers was held by the Senate Committee on Public Health on February 15. The supporters of the bill testified that there are at least one thousand patients suffering from leprosy in the United States, only half of the cases being under control; that the disease is spreading rapidly; that there is real danger of an epidemic, and that segregation is the only means of controlling the disease. Isolation was condemned as unnecessary.

Insane Hospitals.—The serious overcrowding in the fourteen State hospitals for the insane in New York is again pointed out in the report of the State Charities Aid Association to the State Hospital Commission, the situation being characterized as "almost intolerable." A recent census of the hospitals showed the following:

Hospital	Census	Certified Capacity	Overcrowded
Utica	1,991	1,321	379
Willard	2,185	2,015	440
Hudson River	3,361	2,773	588
Middletown	2,165	1,865	302
Buffalo	2,142	1,704	438
Binghamton	2,409	2,110	299
St. Lawrence	2,132	1,776	356
Rochester	1,573	1,282	291
Gowanda	1,222	978	244
Albany	64	8	6
Kings Park	4,445	3,397	1,048
Long Island	829	637	193
Manhattan	4,951	3,596	1,355
Central Islip	4,876	4,017	859
	34,308	27,529	6,779

The overcrowding ranges from 9 to 37 per cent. The report recommends the enlarging of the Middletown State Hospital and the Hudson River State Hospital at Poughkeepsie.

Protest Against Tuberculosis Clinic.—Three hundred residents in the neighborhood of Pleasant Avenue and 118th Street, New York, have protested to the Health Commissioner against the establishment there of a tuberculosis clinic in a building formerly occupied as a clinic for children suffering from diseases of the nose, throat, and eyes. The clinic is declared to be a "menace" to the neighborhood.

Obituary Notes.—Dr. JABEZ DEAN HAMMOND of Chicago, Ill., a graduate of Rush Medical College, Chicago, in 1885, and a member of the American

Medical Association, the Illinois State Medical Society, and the Chicago Medical Society, died at his home on February 15, aged 56 years.

Dr. JAMES LLOYD WELLINGTON of Swansea, Mass., a graduate of Harvard University Medical School, in 1842, and a member of the Massachusetts Medical Society and the Bristol District Medical Society, died at his home on February 11, aged 99 years. Dr. Wellington was the oldest living graduate of Harvard University.

Dr. GEORGE DWIGHT KAHLO, medical director of the White Sulphur Springs, W. Va., a graduate of the Bellevue Hospital Medical College, New York, in 1891, formerly dean and clinical professor of medicine of the Indianapolis School of Medicine, president of the Indiana State Medical Association, and medical director at the French Lick Springs, Indiana, and a member of the American Medical Association and the West Virginia State Medical Association, died suddenly from heart disease at the Hotel Chamberlain, Old Point Comfort, on February 12, aged 51 years.

Dr. W. D. WRIGHT of Powder Springs, Ga., a graduate of the Atlanta Medical College in 1884, died suddenly from apoplexy at his home near Lost Mountain, on February 4, aged 67 years.

Dr. T. H. MURRAY of Greenfield, Iowa, a graduate of the St. Louis College of Physicians and Surgeons in 1898, died suddenly at his home, on February 8, aged 55 years.

Obituary.

HENRY L. ELSNER, M.D.,

SYRACUSE, N. Y.

Dr. HENRY LEOPOLD ELSNER, professor of medicine at Syracuse University, died very suddenly, of heart failure, in Washington, D. C., on February 17. Dr. Elsner was born at Syracuse, N. Y., on August 15, 1855, and after taking his medical degree at the College of Physicians and Surgeons, New York, in 1877, did postgraduate work in Vienna. Returning to his native city in 1880, he became lecturer on clinical medicine in the Medical Department of Syracuse University in 1881, eventually becoming professor of medicine. He was physician to the St. Joseph's Hospital and director of its dispensary medical clinic, also consulting physician to the Women's and Children's Hospital, the newly established University Hospital, and similar institutions of his city; also an ex-president of the Medical Society of the State of New York, the Syracuse Academy of Medicine, and the Onondaga Medical Society, a member of the New York Academy of Medicine, and of many other medical societies. Dr. Elsner was one of the best known clinical teachers in this country and the most prominent physician in northern New York. He was a man of extremely refined, genial, and lovable disposition, charitable to a fault, and denying himself to no patient, however humble, at whatever hour. His exertions in this regard eventually told upon his health, as did the arduous labors upon his massive treatise on Medical Prognosis, which was prepared for the press by him in the Surgeon-General's Library in 1915. His death will bring a void in the lives of hundreds of patients, to whom he was in the truest sense the beloved physician. His many pupils, whom he regarded as a father his sons, will lose a sincere, loyal, and helpful friend.

F. H. GARRISON, M.D.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEDICAL WAR COMMITTEE—R. S. M., SOLDIER'S HEART—R. A. M. C. YEARLY CONTRACTS—CENTRAL AND PROVINCIAL COMMITTEES—DISABILITY FOR ARMY SERVICE—WOUND INFECTION—AYLMER MAY FOR WAR OFFICE—OTHER APPOINTMENTS—OBITUARY.

LONDON, January 29, 1916.

THE Central Medical War Committee has addressed a letter to every practitioner of military age who has not accepted a commission in the R. A. M. C., as well as to the secretaries of all local medical war committees, with the object of enrolling all fit for active service when needed in the army or the navy. It is clear that with the increasing number of soldiers more medical officers will be required and the committee hopes to enroll all of military age, so that further calls of the Director-General of the Army Medical Service may be met with promptitude, regard being had to the needs of the civil population and the circumstances of individual practitioners. Of course the enrolment of all of military age does not imply that all will be called upon to take a commission. The number actually called upon will depend on the demands of the services. The calls will be made in consultation with the local committees and regard given to the system of classification of the central medical committee, the circumstances of individual practitioners, and the opinion of the local medical war committees as to who can be most easily spared. The local committee will advise and cooperate to safeguard the interests of the absent as far as possible. The central committee considers its experience in dealing with the subject during the last few months has made it fully conversant as well as deeply sympathetic with the difficulties most practitioners have in leaving their work, but as thousands have made the sacrifice others may be asked to follow their example. The committee believes further that those who cannot do so will place their services at the disposal of the committee for making arrangements to preserve the practices of those who do enroll.

Among other discussions connected with the time of war, we have had one at the Royal Society of Medicine on the "Soldier's Heart." It was opened in the Therapeutic Section by Sir James Mackenzie, who, after a reference to the experience of your Civil War, said soldiers invalided in our present contest had been consulting him. He had undertaken the inquiry into cardiac disorders for the Medical History of the War, and jointly with Dr. R. M. Wilson examined 400 cases. In 90 per cent. of cases certified as such they were found not to be heart cases primarily and their treatment differed accordingly. So did their appearance and symptoms. Usually they were spare with drawn faces and showed great vasomotor instability. The hands and fingers would be pale but at times red and perhaps florid red; nose red or blue when cold. After rest and feeding they were cold, pasty-faced, and breathless on exertion, easily tired with perhaps pain in the cardiac region, increased rapidity of the beat which may be considerable, say up to 110 or 120, but in other cases there may be no perceptible increase. Some hypertrophy may be met with and some edema. Undue rapidity will be set up by exercise, hence the term "irritable heart." General irritability and restlessness are also com-

mon; in other cases depression, in others again a history of previous illness or exposure to hardship or infection. Sir James looked upon the condition as one of general exhaustion, of which the disturbance of the circulation is only part of the manifestation. Such cases differ from those produced by an organism, though in some it seemed doubtful whether there might not be infection of the heart itself. If the temperature persisted for weeks and no source of infection could be found this was more probable. Persistent pain over the heart when the patient was kept at rest suggested toxic infection. But soldier's heart was due to other systems than the cardiac—say *e.g.* the nervous. The heart itself was benefited by judicious exercise, which should be directed toward helping the body as a whole but not continued after fatigue was perceived.

Dr. R. M. Wilson, who had assisted Sir James Mackenzie in this inquiry, fully agreed with his conclusions. Dr. F. J. Poynton did not think a heart which had broken down in training would ever be strong enough to support military service. At the present time, he thought infection was a most important factor. In some cases it appeared as if the heart had scarcely kept pace in development with the rest of the body; it could not be quite dissociated from the nervous system and it was important to safeguard tall, strong youths from early strain. Dr. E. W. Mitchell endorsed what had been said as to toxemia as also did Dr. Philip Hamill, who related cases and said the psychical factor must first be treated. But many of these hearts were permanently damaged and cases must be carefully followed up so that the next generation may have materials from which to deduce a decision as to the precise nature of the condition. Dr. Florence Stoney said "irritable heart" was only a symptom of Graves' disease. She had for years treated it by x-rays to the thyroid gland. Exophthalmic goiter was at the root of the malady. Drs. Bezly Thorne, Alexander Morison, and T. R. Bradshaw added some remarks and Sir J. Mackenzie replied.

A medical man can enter the R. A. M. C. on a contract for one year's service, but others must join for the duration of the war, but this privilege will not be granted to those who fail to enroll with the present committee, which is in close communication with the War Office. This as well as the Local Government Board and the National Health Insurance Commissioners are fully alive to the needs of the civilian population and are doing all they can to adjust the requirements of the military and civilian medical services to the existing conditions.

As a result of conferences with the Director-General of Recruiting, the Central Medical War Committee, which has local representatives in all parts of the country, has been able to procure and to co-ordinate offers of service in the R. A. M. C. Applications for commissions in this service are decided upon by the War Office after reference to this committee respecting the needs of the civil population in the area concerned in every case, and after consultation with the Insurance Commission, and when necessary with the Local Government Board, and the Board of Education. Arrangements of the same kind exist in Scotland.

Questions in Parliament as to recruits found to be physically unfit elicited that some had been rejected as unfit for any form of military service; others would not be called upon so long as their disability remained. It was hoped that a distinc-

tive badge might shortly be given to men discharged from the army as physically unfit.

Asked as to cases of hammer toes, whether surgical boots would not enable them to serve, the reply was that the medical advisers did not recommend their use and, moreover, if lost or worn out on service they could not be replaced at once. As to men discharged for diseases alleged to have been contracted before enlistment, it was said that each case was considered on its merits by the army medical staff and the commissioners of Chelsea Hospital. The military authorities did not accept responsibility for illness not contracted in the service of the State. It would be for the military officers to say if a breakdown was caused by the service.

Dr. Aylmer May, P. M. O., Northern Rhodesia, has been selected by the War Office to undertake research work on the Western front respecting wound infection. Dr. May, who is now returning from South Africa, has done valuable bacteriological work in Rhodesia and elsewhere.

John Howard, the Brighton philanthropist, has been knighted. Sir John's charities were boundless. A recent one was £30,000 to establish cottage homes for nurses incapacitated by age or illness for their employment. They are intended as a memorial to Nurse Cavell. The Howard Convalescent Home, which has been built and endowed at a cost of £40,000, and the Howard Charity, which gives pensions to deserving persons, are further samples of his charity. The home has been occupied by naval and military convalescents since its opening, Sir John having placed it free of charge at the disposal of Lord Kitchener.

Dr. T. J. Walker of Peterborough, J. P., F. R. C. S., was presented on the 22d ult. with his portrait in oils, painted by Mr. Fiddes Watt, A. R. S. A., with a book containing the names of the 750 subscribers with an inscription testifying their esteem and affection.

Mrs. Mozley of Cheltenham entered her 102d year on the 22d ult. in the full enjoyment of all her faculties. She is one of eleven children in a long-lived family; one died in childhood, but two lived to 97, one to 93, and one each 90, 81, and 77. There are four survivors aged respectively 101, 94, 86, and 84. The great grandmother was a centenarian.

Dr. Andrew Dunlop of Jersey, where he practised since 1868, died there on December 30 at the age of 73. He had been in rather delicate health for some time but able to fill his important duties at the dispensary and other institutions, including presidency of the Jersey Medical Society. He was a practical geologist and contributed articles on the subject to scientific periodicals. He also wrote on medical subjects in the *Edinburgh Journal*.

Dr. Charles Henry Fox, who died on Christmas day in his 79th year at Edinburgh, where he had retired since 1894, was formerly proprietor and physician to an asylum for the insane. He was F. R. C. P., Edin., 1900; M. D. Sl., And., 1861.

Lactic Acid Gargle in Diphtheria.—Buttermilk was recommended by Moffitt as a gargle to nine diphtheritic patients whose throats still contained Klebs Loeffler bacilli after all other clinical symptoms had disappeared. The gargle was used freely, five or six times a day. On the third day after use, an almost pure culture of lactic acid bacilli was obtained from eight of these patients, while the ninth case produced a pure culture on the fifth day.—*Pennsylvania Medical Journal*.

Progress of Medical Science.

1. Address on Sir James Paget and Paget's Disease. Elliott C. Cutler.
2. A Sketch of the Organization for the Care of Transportation of the Sick and Wounded in the British Expeditionary Force in France. Roger I. Lee.
3. The Occurrence of the Wassermann Reaction among Hospital Patients. Albert A. Hornor.
4. Treatment of Central Nervous System Syphilis. I. Chandler Walker.
5. The Treatment of Syphilis. C. Morton Smith.

3. The Occurrence of the Wassermann Reaction Among Hospital Patients.—Albert A. Hornor gives the results of the application of the Wassermann reaction as a routine measure among 500 patients admitted to the Fourth Medical Service of the Boston City Hospital. Eighty-seven of the 500—that is to say, more than one in every six—had a positive test either with the old Wassermann reaction or the test modified by the use of cholesterinized antigen. In only eighteen of these cases was a probable diagnosis of syphilis made before the Wassermann report was received. This means that 13.8 per cent. of the cases not showing obvious signs of syphilis showed a positive test. In this series the rarity of a positive Wassermann reaction with alcoholism seems to bear out the statement of several later observers to the effect that alcohol will vitiate a positive reaction. There was a marked frequency of positive reactions among cardiac conditions of one sort or another. From this study the writer concludes that one may not tell in many of the cases admitted to the medical wards in general hospitals whether or not the patient's condition may be complicated by syphilis. Surely if one medical admission out of every six has a positive Wassermann reaction, the doing of this test as a routine is valuable.

4. Treatment of Central Nervous System Syphilis.—I. Chandler Walker gives a summary of the treatment and its results in the first forty cases of central nervous system syphilis at the Peter Bent Brigham Hospital. Cases of tabes, general paresis, cerebrospinal syphilis, and syphilitic meningitis are considered; cases of purely cerebral syphilis are excluded. In those cases treated with salvarsan, large doses were used; in those treated with serum intraspinally 20 to 25 c.c. of undiluted serum were used. Dr. Walker concludes that cases of syphilis of the central nervous system with only a positive blood react well to salvarsan; those with a positive blood and spinal fluid may react well to salvarsan alone, but they do much better when intraspinal serum is used in conjunction with salvarsan, and some that do not react well to salvarsan alone react well to the combined method. One may get improvement in general paresis from the combined treatment. Cases of syphilitic meningitis may clear up with salvarsan alone, but the combined treatment is quicker. Cases of central nervous system syphilis with a negative blood and a positive spinal fluid react readily to a salvarsanized serum intraspinally alone, even when salvarsan has failed. The spinal fluid of the cases treated with salvarsan has become negative in two cases, whereas the spinal fluid of seven cases treated with the serum alone has become negative. The writer feels that salvarsanized serum is a great asset in the treatment of syphilis of the central nervous system, and in the general run of cases he thinks the Swift-Ellis method is of great value and that this method in connection with mercury intramuscularly is the best treatment of syphilis of the central nervous system at this time.

5. The Treatment of Syphilis.—C. Morton Smith states that they have been able to demonstrate the *Spirochæta pallida*, with dark field, in 96 per cent. of

the smears made from the last ninety-seven primary sores examined at the Massachusetts General Hospital. He finds the India ink method inexact and unreliable. After reviewing salvarsan, mercury, and iodide therapeutics, he says that until recently a physician considered his whole duty was to his patient; but it is now a part of his follow up work to see that the patient continues treatment, and that the members of his family and friends who may have given or received infection, come for examination and treatment. The responsibility of bringing these suspects is placed on the patient if possible. At the present time there is no means whereby a patient with syphilis can receive aid from town or State without automatically becoming a pauper. The State should bear the expense of protecting the public from the infectious syphilitic. This being an age of preventive medicine it should be applied to the treatment of syphilis in three ways: (1) By training young people to lead clean, proper lives; personal optimism or overconfidence is responsible for a greater number of syphilitic infections than ignorance of the disease. (2) By prompt, intensive, intelligent treatment of every infected individual, begun during the primary stage, if possible, and continued until the patient is released by a clinical opinion supplemented by serologic findings. (3) By the enforcement of our present health laws.

1. Recent Developments in the Treatment of Leprosy.—Victor C. Heiser reports later results of the treatment for leprosy described in the MEDICAL RECORD of August 29, 1914. The treatment, as then noted, consists of injections of a mixture of chaulmoogra oil 60 c.c., camphorated oil 60 c.c., and resorcin 4 grams. This method is now being followed in the treatment of leprosy in the Straits Settlement, Federated Malay States, India, Hawaii, Ceylon, and in a number of institutions in the United States. The injections are usually made at weekly intervals in ascending doses, the initial dose being 1 c.c., and this is increased to the point of tolerance. Much difference exists among the cases as to the amount of the mixture the patients are able to take. Quicker results are apparently obtained when it is possible to inject the mixture into large leprosy deposits, or to divide the dose by injecting it into a number of smaller infiltrations. Attention is drawn to the fact that no strychnine is used. In the United States Public Health Reports a total of five cases have been reported as having been cured and having remained cured for a period of over two years. Reports from Manila state that twenty-three more lepers have been discharged from the leper colony as cured. When Dr. Heiser left the Philippines in March, 1915, he says there were probably 200 other cases showing noticeable improvement. He does not claim that anything like a specific for leprosy has been found, but his experience shows that chaulmoogra oil gives more consistently favorable results than any other treatment that has come to their attention, and holds out the hope that further improvement may be brought about. The treatment is apparently equally efficacious in all forms of the disease. In order that further observations may be made in all parts of the world, the International Health Commission is taking steps to circulate details

of the chaulmoogra oil treatment in all countries in which leprosy occurs.

2. Treatment of Grippe.—Beverley Robinson offers the following prescription as a really efficient and harmless remedy for grippe:

R Ammonii salicylatis grs. iij
Caffeinae. gr. ʒi

M. Fiat capsula No. 1.

M. Sig.: Two of these capsules should be taken by an adult, every two hours, for four or five doses, and then every three or four hours.

If the capsules cause slight nausea, which is rare, this may be relieved by drinking a little vichy with each dose. He is also inclined to think that these capsules may be used as a preventive measure against grippe.

3. So-Called Grippe.—J. B. Rucker has investigated, since the middle of December last, 20 cases of acute catarrhal disease so simulating grippe that it has been commonly spoken of as such and has found the influenza bacillus only twice, and in those only in stained smears made directly from the swabbings, but has not in a single instance been able to isolate it. In eight instances he found a pneumococcus, typical at least in morphology; in six, atypical pneumococcus or *Streptococcus mucosus*; in all 20 cases he found a small Gram positive biscuit shaped diplococcus. He says that if it were not for the fact that 75 per cent. of normal throats contain either typical or atypical forms of the pneumococcus, and in all or nearly all normal throats the small Gram positive diplococcus is found he should be inclined to think that this little diplococcus was the probable cause of the trouble in these 20 cases. In only two of the 20 cases did these small Gram positive diplococci show pathogenicity in animals, and in only one animal did symptoms simulating grippe in man appear. The writer expresses the opinion that it may be possible under some unknown conditions that the virulence of the ever-present Gram positive diplococci becomes enhanced, or the resistance of the human organism becomes lowered, or both, the natural combative forces of the tissues are overcome, and the diplococci gain entrance to the lymph channels and blood stream and a general bacteriemia results, causing the symptom complex of the disease commonly known as grippe. Complement fixation methods, using the diplococcus as antigen, seem to be the most promising to determine the question as to the etiological relation of this organism to grippe, inasmuch as the inoculation of laboratory animals is unsatisfactory.

6. The Diagnosis of Brain Tumor.—H. Climenko reports a number of cases which serve to bring out certain facts with reference to the diagnosis of brain tumor among which are the following: If convulsions begin first at or after middle-age, the diagnosis of epilepsy should not be made. Every such case which the writer has had the opportunity of observing carefully, sooner or later revealed its organic origin. The diagnosis of brain tumor may be clear and yet at operation no tumor may be found and no evidence of increased intracranial pressure, yet on the other hand, by judicious and careful study one may be able to diagnose tumor, localize it, remove it, and render the patient's condition comfortable indefinitely. It is the clinical developments of the case and the proper interpretation of symptoms that are of the greatest importance. The writer urges that every case of brain tumor be carefully observed and reported, since it is the clinical and not the experimental study of these cases that must add to our knowledge of diagnosis in these cases.

8. Fracture of the Skull.—Frederick R. Barnes

and Morris A. Slocum present a series of fractures of the skull which show the value of their treatment by withdrawal of spinal fluid by lumbar puncture. From 1910 to 1913, at the German Hospital, Philadelphia, lumbar puncture was not done and all but one case ended fatally. During the next three years, in a series of 27 cases, the majority of which were tapped, the mortality was 40 per cent. From their results the writer thinks the following conclusions are tenable: 1. Lumbar puncture should be done in every case of severe head injury, both for diagnosis and treatment. One tap does not suffice; daily puncture until recovery is best. 2. Trephining should be reserved until the last. Definite indications only should warrant opening the skull. 3. Patients often get well if let alone. Too much surgical interference is a mistake. 4. The intraspinal injection of hexamethylenamine is harmless, but is of little value in our opinion.

1. **The Purification of Water Supplies.**—Edwin O. Jordan states that the question of water purification is limited to the hygienic aspects of the subject. Clarification of a muddy water, removal of an excess of iron, softening of a hard water are all ends desirable in themselves, but they are not purification in the sense in which that term is here considered. Consideration of purification of water is restricted to the methods of rendering a contaminated or potentially dangerous supply safe for use. The present necessity for water purification in civilized countries is a consequence of two factors: first, a greatly increased demand for water under modern conditions of life; second, the increasing density of population on most parts of the earth's surface. Where surface waters are resorted to, the need of purifying them is so plain in some cases that there can be no question of its imperative-ness, as with the Merrimac River, used by the city of Lawrence, Mass.; the Hudson River, used by the city of Albany, and the Schuylkill River, drawn on by Philadelphia. Water purification in these cities has been followed by a marked diminution in the amount of certain diseases. The modern methods of purification are (1) storage, by which a high degree of natural purification can be effected; (2) slow sand filters; (3) rapid sand filtration, and (4) germicidal treatment. When a polluted water that serves as a source of municipal supply is treated by slow sand filtration, the most conspicuous immediate change in the health of the community is a drop in the typhoid death rate. The results of rapid or mechanical filtration are essentially similar to those of slow sand filtra-

tion. Excellent results as regards bacterial efficiency and security from typhoid infection are achieved by bleaching powder and by liquid chlorin treatment. At the present rate of progress, water-borne diseases in the cities and larger towns of this country will be relatively rare within ten years.

2. Pellagra: Causation and a Method of Prevention.

—Joseph Goldberger gives the following summary of some of the recent studies of the United States Public Health Service: 1. Diet is the common factor in the various methods of treatment recently advocated. The marked success claimed for each of these methods must logically be attributed to the factor (diet) which they have in common. 2. The value of diet in the prevention of pellagra has been tested at two orphanages and at an asylum for the insane, endemic foci of the disease. Marked increases in the fresh animal and leguminous protein elements of the institution diets were made. Of 209 cases of pellagra observed at the two orphanages during the spring and summer of 1914, not less than 172 completed at least the anniversary date of their attack under observation. In only one of these 172 pellagrins, following the change in diet, was there recognized evidence of a recurrence, although on the basis of experience elsewhere, from ninety-nine to 130 might reasonably have been expected. Nor was any new case observed among the nonpellagrin residents, 168 of whom completed not less than one year under observation. Of the group of pellagrins on the modified diet at the insane asylum, seventy-two remained continuously under observation up to Oct. 1, 1915, or at least until after the anniversary date of their attack of 1914. Not one of this group has presented recognizable evidence of a recurrence, although, of a group of thirty-two controls, fifteen have had recurrences. Pellagra may, therefore, be prevented by an appropriate diet without any alteration in the environment, hygienic or sanitary, including the water supply. 3. At an isolated convict camp, previously free from pellagra, with an average population of from seventy to eighty white males, eleven volunteers were segregated and, after a preliminary observation period of two and one-half months, placed on an abundant but one-sided, chiefly carbohydrate (wheat, corn, rice) diet, from which fresh animal proteins and legumes were excluded. At least six of these volunteers developed pellagra. This result would appear to have been brought about by the diet on which they subsisted. 4. A definite conclusion as to the intimate mechanism involved in bringing about or in preventing the disease by diet cannot be drawn from the available data. 5. For the practical purposes of preventive medicine, it would seem to be of fundamental importance to recognize that the pellagra-producing dietary "fault," whatever its intimate nature or however brought about, is capable of correction or prevention by including in the diet suitable proportions of the fresh animal and leguminous protein foods.

3. **Drug Addiction.**—Joseph McIver and George E. Price give an analysis of 147 cases at the Philadelphia General Hospital. These patients were treated by the original Lambert method, by the Lambert method without the Belladonna R, by the Lambert method without free purgation, by gradual withdrawal, and by gradual withdrawal with free purgation. They conclude that while the medical profession has had much to do with the formation of the morphine habit, and in former years with the development of the cocaine habit, it has had little or nothing to do with the remarkable development and spread of the cocaine, and especially the heroine, habit of the last few years. Farr has drawn a similar conclusion. Degeneracy, as

shown by actual signs of developmental arrest, is present in a large proportion of cases of drug addiction. The majority of narcotic drug habitués are not also addicted to the excessive use of alcohol. Heroin is not as deleterious in its effects as morphine, and can be much more readily withdrawn. The most valuable unit in the Lambert treatment is the method of free purgation. The Lambert treatment, while better than the old method of very slowly withdrawing the drug, is not as satisfactory as gradual withdrawal combined with free purgation and medication to meet the individual requirements. Any treatment which does not take into consideration the presence of the antitoxic substance in the body long after the drug has been withdrawn, and provides for the observation and care of the patient during this time, is almost certain to be void of permanent results. This is the era of preventive medicine, and the old axiom that "An ounce of prevention is worth a pound of cure" is certainly true in drug addictions. It is the duty of every physician heartily to cooperate with the federal authorities to restrict the use of opium derivatives and cocaine to their proper medical functions.

4. Goiter.—Charles N. Dowd makes an analysis of 137 cases, reviewing the results of the work which the surgical staff of Roosevelt Hospital has done on goiters for the five years ending Jan. 1, 1915, including the work he had done in other institutions. The study has been carried on in a search for the best method of dealing with goiters, and as a result the writer says the following deductions seem to be fair: 1. For non-toxic patients who suffer from pressure symptoms or from neck deformity, cyst enucleation or partial thyroidectomy are extremely satisfactory procedures. The symptoms are relieved, and the likelihood of later toxicity is almost abolished. 2. For mildly toxic patients, operation is also very satisfactory. When the toxic symptoms develop in connection with pre-existing goiter, cure is almost certain. When they develop in the early stages of thyroid hyperplasia cure is usually obtained, but cannot be expected with the same confidence. The operation may be by partial thyroidectomy, cyst enucleation, artery ligation, or boiling water injection, according to the peculiarities of the case. 3. The patients with advanced exophthalmic goiter present the most difficult problems. For their successful treatment many elements must be considered, including the complex nature of the ductless glands, their interdependence on each other and on nervous and chemical influences from other parts of the body, and the various therapeutic measures which interrupt this vicious chain of disturbance. The hyperplastic thyroid gland seems to be the cause of many of the symptoms, and it is the organ most easily attacked in our effort to control these symptoms. The treatment consists largely in endeavor to control its overactivity. Rest is an important element in this treatment. The injection of boiling water (Porter) has an undoubted influence, and can be used for patients too ill for more radical measures. The ligation of the thyroid arteries is often very beneficial, and can be used in preparing patients for hemithyroidectomy or as a substitute for that procedure. The excision of a part of the thyroid gland has been followed by so many satisfactory results that it must be considered our most reliable therapeutic measure. The administration of drugs and animal extracts, and the use of the Roentgen ray may be beneficial. The choice of these procedures should depend on the condition of the patient. If that choice is judicious, nearly all of these patients can be brought to a condition of marked improvement.

5. Needless Surgical Operations from Failure to Recognize Tabes Dorsalis.—John W. Nuzum says that in the past five years (1910-1915) over 1,000 cases of tabes dorsalis have been carefully studied in the Cook County Hospital and the conclusions arrived at are as follows: 1. Of the 1,000 tabetics, 8.7 per cent. have been subjected to laparotomy under mistaken diagnosis one or more times. 2. The "crises" of tabes have largely influenced the surgeon in his decision to operate. This statement is supported by the fact that 65 per cent. of the 87 patients operated on presented visceral crises. In 17 per cent. of these the "crises" were the *initial symptoms* of their disease. 3. Mistaken diagnoses and resulting operations occur chiefly through failure to examine the nervous system. 4. Gastric ulcer, gallbladder disease, and appendicitis are the diagnoses most frequently made. 5. Tabetics subjected to severe successive laparotomies have, as a rule, been operated on by as many different surgeons. 6. A history of paroxysmal attacks of vomiting, rheumatism, paresthesias, bladder disturbances, or fractures without physical violence should excite interest to exclude tabes dorsalis. 7. The cytodiagnosis of the cerebrospinal fluid, together with the Wassermann reaction with the spinal fluid, are of inestimable value in doubtful cases.

7. Routine Wassermann Examinations.—I. C. Walker and D. A. Haller have tested 4,000 individual cases and offer the following conclusions: 1. Syphilis is even more prevalent than ordinarily supposed. 2. A routine Wassermann test is of the greatest value in a general hospital. 3. Neurological cases should always be tested, and particularly all cases of epilepsy. 4. Cases of unsuspected syphilis greatly outnumber those frankly syphilitic among patients applying for treatment in a general hospital. 5. The common infectious diseases—typhoid fever, pneumonia, tuberculosis, and scarlet fever—have no influence toward causing falsely positive reactions. 6. We find no argument in favor of a belief that chronic nephritis with or without hypertension is due to syphilis. 7. Diabetes in our series showed a fairly high percentage of positive reactions, and in one or two cases the coincidence of this disease and the onset of diabetic symptoms was suggestive but in no way conclusive. 8. The well-known affinity of the *Spirochaeta pallida* for vascular and nervous tissues is most marked, and it is unfortunate that the early lesions of the disease are so slight as to be so often unnoticed and consequently untreated at this time, when later and more serious lesions could be prevented. 9. Syphilis of the liver presents a most difficult problem in differential diagnosis. The presence of icterus should make one wary of the interpretation of any but strongly positive tests.

10. The Significance of Certain Roentgenographic Findings in the Gastrointestinal Tract.—C. L. Palmer says that the observations recorded were made on a series of fifty gastrointestinal cases studied by all the usual clinical methods, including roentgenograms following a bismuth meal, and the result throws some new light on the significance of certain roentgenographic findings. He offers the following summary: Normally the stomach can change its position without the help of alteration in body posture. When this mobility of the stomach is lacking it is either due to restraining forces which prevent the movement, or else to lack of power to move. The former is the most frequent cause for lack of change of position of the stomach. Persistent supraposed stomach is due to a restraint and not to lack of power. This restraint is most frequently exercised by adhesions due

chiefly to cholecystitis, chronic appendicitis, traumatism (previous operation), or gastritis due to syphilis, cancer, or ulcer. Persistent infraposed stomach is not as frequent as supraposed stomach. It is caused by restraint or lack of power to move, most frequently lack of power, which is the case in chronic gastroenteroptosis with relaxation of the abdominal walls. Long retention of the gastric contents (twenty-four hours or longer) is chiefly due to one cause, namely, cancer of the stomach. The other chief cause is long standing chronic cholecystitis. Retention for shorter time (six to twenty-four hours) has for its most frequent causes cicatricial contraction of pylorus due to healed ulcers, chronic appendicitis, chronic cholecystitis, typhlitis, and syphilis. Pylorospasm does exist, but it is not always present when extragastric lesions are prevalent. It probably depends on the reflex excitability of the individual's nervous system. Diagnosis made by judging from the roentgenograms, together with the history of the case and other clinical evidence obtainable, was correct in nearly every case. This was demonstrated in the majority of the cases by subsequent operation or necropsy. In most of the others it was shown with a satisfying degree of probability by the subsequent course of the case. Roentgenograms have revealed certain facts which can be demonstrated by other means. The most prominent of these are the obstructive lesions which are as a rule located either in the pylorus of the stomach or in the region of the cecum and are usually due to definite conditions. By the use of the stomach tube in gastric analysis, fecal examinations, the charcoal test, Bastedo's test and careful analysis of clinical symptoms and physical signs, it is possible in a certain number of cases to make a very accurate diagnosis without the use of the ray. In all cases which are readily diagnosed without the ray, however, roentgenograms should be taken and carefully interpreted along with laboratory tests, clinical history, and physical findings, in order to obtain a clear diagnosis.

6. A Fatal Case of Anthrax: Infection by a Shaving Brush. E. W. G. Masterman.

1. **Gunshot Wounds of the Chest.**—John Rose Bradford deals with this subject from the point of view of the physician and confines himself more particularly to a discussion of hemothorax and pneumothorax. He calls attention to the fact that hemothorax may result from a wound of some other region than the chest, especially the neck, the arms, or the upper abdomen; further hemothorax and even pneumothorax may be found on the side opposite to the wound of entry in the chest and without any obvious or marked lesion on the side of entry. While the physical signs of hemothorax are in many respects similar to those of pleural effusion, there are certain differences. The diaphragm on the affected side is extraordinarily high. It is exceptional in a case of hemothorax for the stomach resonance at the lower costal margin to be replaced by dullness, and it is not very unusual on percussion of the front of the chest for the stomach note to merge into the skodiatic resonance of the upper part of the front of the chest. Owing to this a hemothorax may be overlooked or may be diagnosed as a pneumo-

thorax. In hemothorax the skodiatic phenomena are much more marked than in pleural effusion. Loud tubular breathing, increased bronchophony, and pectoriloquy are more marked and more often to be detected in hemothorax than in pleural effusion, and finally the heart's apex undergoes changes in position that are peculiar. Another peculiarity of hemothorax cases is the rapidity with which retraction of the affected side may develop when the effusion is not aspirated. The writer states that in the early months of the war many of these cases were treated by expectant methods, but they were liable to be in feeble health for a long time, and so they began treating cases by aspiration with oxygen replacement to avoid too sudden expansion of the lung. Two distinct benefits ensue from this method of treatment: the lung rapidly re-expands and the pyrexia which is often present rapidly subsides, so that the patient quickly regains his health. This treatment has been very successful, no untoward results having been observed and in a large series of cases not one of secondary hemorrhage has occurred. About 25 per cent. of their cases of hemothorax were infected and in cases of this class early recognition of the existence of infection and prompt drainage by resection of a portion of a rib greatly reduces the mortality. In the early months of the war pneumothorax was constantly being diagnosed, but with increased experience they now believe that pneumothorax in association with gunshot wounds of the chest is uncommon, only twelve instances having been found in a series of 500 cases. This complication produces great complications and difficulties in regard to treatment. In some of their cases good results were obtained by aspirating them for the purpose of withdrawing the air and getting a certain degree of expansion of the lung prior to resection of a rib. This procedure is accompanied by certain risks and hence should only be done with the guidance of pressure readings and by the sensations of the patient. In a case of pneumothorax with urgent dyspnea the intrapleural pressure may be that of the atmosphere and aspiration can therefore do no good, but on the other hand it may be found that the pressure is positive and that by drawing off the air a negative pressure may be produced and the lung gradually expanded.

2. **The Surgical Treatment of Gunshot Wounds of the Chest.**—H. Morrision Davies advocates early, and, if necessary, repeated exploratory punctures as essential to successful treatment of gunshot wounds of the chest, since without it it is not possible to differentiate, in the majority of cases, between a simple pleural effusion, a hemorrhagic effusion, a fluid hemothorax, a clotted hemothorax, or at times an infected hemothorax. When done in the proper way an exploratory puncture is accompanied by no danger, no distress to the patient, and practically no discomfort. In the treatment of fluid hemothorax the "oxygen replacement" method, first described by the writer in 1912, should be used and is without danger of edema of the lungs or recurrence of the hemorrhage. When clotted hemothorax is present an opening must be made through the chest wall and adequate room can be obtained only by the subperiosteal resection of some 5 cm. of rib. By such an operative procedure convalescence is more rapid and more complete than by the "wait and see" method. In hemothorax, in which there is infection, the operation of removing a segment of rib possesses advantages over other procedures and takes only a few moments longer. In discussing the treatment of pneumothorax the author recommends as an emergency measure, when intra-

pleural pressure is endangering the life of the patient, that a fine bore hollow needle (0.5 mm.) be thrust into the pleural cavity; the intrapleural air under pressure will escape slowly, giving the patient great relief. The beneficial effects of this trifling procedure may be permanent in the mildest cases. It is only in those cases which become serious because of a reaccumulation after some hours that any other line of treatment is indicated, as establishing a temporary fistula between the pleural cavity and the outer air. The necessity of having a manometer connected with the pleural cavity and of registering constantly the variations in intrapleural pressure and of having means of controlling the same during operative interference cannot be too strongly emphasized. With reference to the removal of foreign bodies from the lung the writer believes that this step should not be taken unless the foreign body is producing definite symptoms which are likely to be progressive, and that even then the operation should not be done until the initial reactionary inflammation has subsided.

3. The Rationale of Chemotherapy in Syphilis.—J. E. R. McDonagh reviews the line of argument by which, while he was working at the rationale of the Wassermann reaction, the thought had suggested itself to him that the action of salvarsan, which he considered as a peroxidase, might be enormously enhanced if a markedly absorbed sulphur compound could be prepared. He prepared two basic and two acidic compounds. The first acid compound was the acetyl derivative of diorthoaminothiobenzene and the second acid compound was the condensation product of the base with chloracetic acid. These two products were both extremely painful and their therapeutic action was practically nil. The two basic compounds were diparaaminothiobenzene and diorthoaminothiobenzene. The therapeutic action of the former of these was not as good as the latter, which has been called for short "intramine." This preparation is absolutely non-toxic and when compared with salvarsan the writer has found that in the primary and generalization stages of syphilis salvarsan is superior to intramine, but that in the recurrent stages the opposite was the case. He has treated over eighty cases with intramine and the results, provided the rules suggested are adhered to, are very much better than even the best of those obtained with salvarsan when it first came out. Several cases had healed at once with one injection, when they remained practically uninfluenced by an arsenic preparation and subsequent treatment with mercury and iodides.

5. Influence of Febrile Conditions on Inoculation Agglutinins.—H. L. Tidy finds that inoculation agglutinins are diminished or entirely removed by febrile conditions. It is possible that they are converted into agglutinoids. In certain cases they may return but usually they do not. A positive agglutination reaction to *B. typhosus* after the fifth day of pyrexia has the same value in an inoculated as in an unoculated person. Immunity conferred by inoculation may be affected at the same time as the inoculation agglutinins.

6. The Temperature Necessary for the Destruction of Lice and Their Eggs. A. W. Bacot.

1. Gunshot Wounds of the Knee Joint.—A. L. Lockwood describes the method of procedure and operation employed at a base hospital in the treatment of wounds of the knee of various kinds, as tunneling wounds without fracture, open penetrating wounds, wounds with localized fracture of the bones forming the joint, with possibly a foreign body still embedded in the bone, and wounds in which a great part of the knee joint is laid open. The series coming under the observation of the writer consisted of sixty cases. In this series there was one death; there were three amputations, three cases of ankylosis, and four in which motion was limited, while in forty-nine free movement was obtained. The points which the author emphasizes are: 1. That all foreign bodies, whether metal or loose bone, should be removed from the knee-joint at the earliest possible moment. 2. Perfect immobilization is absolutely necessary. Do not start passive movements too early; wait at least three weeks after the inflammation has subsided. 3. Absolutely complete excision of all necrotic or even edematous tissue. 4. The capsule should be closed at the first operation if at all possible. 5. Antiseptics, other than the ones mentioned, should not be introduced into a joint. 6. Tubes should never traverse the joint surface as in Barnard's method. 7. Patients should not be moved till one is satisfied that infection has been successfully combated.

2. Epidemic Cerebrospinal Fever: the Place of the Meningococcus in Its Etiology.—Edward C. Hort discusses the theory that the meningococcus of Weichselbaum is in itself the primary infective agent in epidemic cerebrospinal fever and concludes that at present there is available no adequate evidence to show that this organism is itself the causal agent of the disease cerebrospinal fever. On the contrary, the experimental evidence which he presents distinctly suggests that it is not. He found that the fresh filtrate of cerebrospinal fluid in the two cases examined contained a virus which was highly infective to monkeys and states that the true bacterial content of the body fluids in this disease can only, as a routine procedure, be satisfactorily determined by using the fluids themselves as the optimum medium of growth, combined with injection into suitable animals in the fresh condition. Incubation of the body fluids infective to monkeys in the uninoculated state, appears to destroy their infectivity, and in doing so, to throw some light on the ancestry of the meningococcus. These conclusions have a certain influence on the therapeutic and epidemiological control of the disease. Although the meningococcus appears itself to be incapable of producing the disease, it should be searched for as vigorously as heretofore, since its presence is a valuable danger signal that the true infective agent is, or has been, present. Attempts to prepare antisera to the meningococcus do not appear likely to lead to effective control of the disease. Confirmation of the infectivity of fresh cerebrospinal fluid would justify the preparation and trial of effective antisera thereto in the treatment of the disease. Attempts to destroy the meningococcus in the nasopharynx of contact carriers would appear to be of less value than an attempt to determine what the true infective agent of the disease really is. To this end attention should be particularly directed to filtrable organisms in the nasopharynx and the cerebrospinal fluid of acute cases.

4. Gassing Accidents from the Fumes of Explosives.—Louis G. Irvine outlines the typical sequence of symptoms in poisoning by nitrous fumes, consisting of initial symptoms of irritation, then a latent period of several hours duration, during which the patient

may and usually does feel quite well, and after this interval a sudden onset of acute symptoms, due to rapidly progressive and inflammatory edema of the lungs. He cites cases falling into two groups, namely, those due to exposure to the fumes of explosives immediately after blasting and those in which the exposure to the fumes occurs several hours after blasting. In the treatment of these patients emesis is produced as soon as possible in all cases by the hypodermic injection of apomorphine. This is followed by stimulants, ammonia, or preferably pituitrin. Atropine may prove useful in the latent stage. In the acute stage wet cupping of the chest, back, and front relieves the symptomatic distress. It should be followed by poulticing, or better, by jacket mustard water fomentation, applied very hot and changed every hour. Free blood-letting should next be performed and should not be delayed until the condition of the patient becomes grave. Venesection should be followed by saline infusion and the procedure repeated if necessary. Oxygen should be given intermittently to relieve and tide over the asphyxial condition. Injections of 1 c.c. pituitrin should be repeated every four hours. This line of treatment has been followed by marked success in a considerable number of cases, although when the condition of acute edema is well established probably a majority of the cases will die in spite of treatment.

January 3, 1916.

Infectiousness of the Cerebrospinal Fluid in Syphilis.

—Frühwald and Zalozecki mention the great importance of the study of this fluid in syphilitics. Ravant first showed an increase of cellular elements in this disease (pleocytosis). Next came the discovery of increased albumin and in turn the Wassermann reaction. Finally after prolonged search the spirochete was found and positive inoculation tests followed. The aim of the authors had been to learn more about the infectiousness of the fluid under various circumstances. But one of them (Zalozecki) was called to the front, while the other found trouble in obtaining and feeding the rabbits necessary for prosecuting the work. In the meantime he (Frühwald) has gone ahead as best he could. The spirochete was found in the cerebrospinal fluid as far back as 1905 in a patient in the papular stage of syphilis. This find proved to be an exception, for other cases both of secondary and tertiary syphilis and tabes gave negative results. A year later a positive result was obtained by inoculating an ape with cerebrospinal fluid from a patient with papular syphilis. Several years later the spirochete was seen with the ultramicroscope in the centrifuged sediment of the fluid of a woman in the first year of syphilis. The patient had been stricken with total left hemiplegia. Curiously enough a parallel case was reported at about the same time. In 1913 Nichols and Hough reported a remarkable case in a man of twenty-five. Eight months after infection (he had received two salvarsan injections) he developed numerous evidences of cerebral syphilis with a psychical component. The cerebrospinal fluid was negative to the Wassermann reaction, which, however, was positive in the blood. However, the fluid was inoculated into a rabbit's testicle and a lesion slowly developed which contained the spirochete. Experiments, heretofore sparse and scattered, now began to be reported in large numbers. Many positive finds were reported for the secondary period. Results in metasymphilis were at first mostly negative, but positive finds in time became cumulative. In several cases paralytics showed the "four reactions." The authors now report such finds as they have ob-

tained to date. Eight patients with primary syphilis, as might have been expected, gave negative results. In three patients with recent secondary syphilis a positive result was obtained in one. In seven patients in a more advanced secondary stage, two gave positive results. But one patient with tertiary syphilis was tested and with negative result. Finally in three miscellaneous cases classed as "nervous" only one, a case of paresis, gave positive finds. In general the positive find was the inoculation test made in the rabbit's scrotum. In four cases there were positive spirochete finds. In but one case was the Wassermann reaction positive. A collected series of spirochete finds made by all investigators to date shows the total positive to be fifteen. To this number should be added three positive finds in victims of inherited syphilis. In summing up the authors state that positive spirochete finds are very few (doubtless too few to be of use save in very obscure cases). The inoculation test is very slow and the lesions set up are sometimes so slight as to be overlooked. The Wassermann is often negative at the time of the test, even when nervous symptoms are present. Thus far no laws of infectiousness of the fluid can be postulated.

Münchener medizinische Wochenschrift.

January 4, 1916.

Blood Transfusion in Military Surgery.—Eloesser of Stanford University, now surgeon at a reserve hospital in Germany, mentioned the surprise one must feel to learn that such a life-saving measure as transfusion is seldom used on the battlefield. Even in home hospitals it is often in demand for secondary hemorrhage. At the front the man who is bled white by primary hemorrhage surely demands this resource. Of course the failure to apply it rests upon the complicated technique required and the inexperience of most of the surgical rank and file with surgery of the blood-vessels. At present more simple methods are being evolved, and recently one has been published by Sauerbruch in the interest of simplicity, but the author prefers one which he has modified from that of a San Francisco colleague, Pope. This involves uniting artery and vein with a rubber tube having at either end a glass cannula. The time required for local anesthesia, for dissecting out the radial artery of the donor and vein of the recipient, and for adjusting the apparatus is not stated. The transfusion lasts from fifteen to twenty minutes, and the author does not pretend to say how much blood passes from one subject to the other. No cases from the front have been reported in which the method has been tested, but the author has transfused ten patients with acute or chronic hemorrhages, the latter of septic origin. The management of the blood vessels does not appear to differ from the various American methods. The sharp V-shaped incision is used to admit the cannula, and the latter is modified from Brewer's all-glass cannula. Temporary ligatures and clamps are used upon the vessels. All parts which come in contact with flowing blood are wet with sodium citrate solution. All blood which escapes into the wound is quickly wiped away with pledgets wet with the same fluid. The outfit is very simple—in fact, no special apparatus outside of the cannula is required. For clamping a wire safety pin is used.

Atropine in Eclampsia Infantum.—Rascher states that there is hardly any literature on this subject which is accessible to him. In the country in which he practises there is often great need of some quickly acting resource for infantile convulsions. He describes a case in which atropine was used and hopes the remedy will be tested by colleagues. He was summoned to treat a three year old

girl for convulsions. Not long before he had heard that an atropine derivative had been used for similar purposes and he resolved to exhibit an ordinary atropine sulphate solution as carried in ampoules. The child had had a series of convulsions without apparent cause. Her temperature was high and the mother looked forward to an attack of some infectious disease. The paroxysms were now becoming serial and something had to be done. Laryngospasm coexisted. The author mixed the contents of an ampoule (one thousandth of a gram of atropine) with 9 c.c. boiled water and injected a syringe (making, he says, about 1/650 of a grain). The symptoms improved almost immediately and no more crises occurred. In seeking a cause for the convulsions the most suspicious fact was her diet, she having been subsisting wholly on boiled milk. It was in 1907 that Bösl reported a similar result from the use of an atropine derivative made by Merck, which, however, seems to have dropped out of sight. The two results certainly warrant a test of the alkaloid in these cases.

Experiences in the Treatment of Soldiers with Nerve Injuries and Nervous Affections.—Lewandowsky first mentions injuries of the peripheral nerves. The operations of neurotherapy and neurolysis may have been performed too late or not at all. There is an extremely conservative view, held only by a small minority, of delaying all intervention after nerve injuries for four or five months, on the principle that spontaneous repair may occur during this period. But even this modest rule is not followed. There are many whose injuries date back from six months or more who are either pronounced inoperable, or upon whom intervention is deferred, or who are promised recovery from paralysis without operation. The neurologist and the regular military surgeons are often at odds on such matters, especially because little is known of the operative prognosis. The author recommended operation in a series of forty cases, but in the great majority of cases nothing was done. Of seven in one battalion recommended for operation but one was subjected to intervention. Five refused operation and were released as incapable of service. Of those with injuries of the spinal cord, all were allowed to die. A permanent water-bath could have prevented decubitus at least in some of these cases. The dangers in cranial and cerebral injuries are bound up largely in the sudden or gradual evolution of abscesses, in both open and closed wounds. It is not sufficiently well known that the sudden appearance of headache, vomiting, and confusion indicate abscess formation, even in the absence of fever. In regard to functional neuroses—hysteria, neurasthenia, and traumatic neuroses—the diagnosis can be made with certainty in 95 per cent. of cases, *i.e.* in not more than 5 per cent. is there a difficulty in excluding organic disease, although an organic base of some kind may of course be imagined for many seemingly functional neuroses which develop in warfare. The psychogenic factors—fright and the unconscious wish to escape from military service—are sufficiently powerful to be regarded as determining the neuroses. A predisposition is also frequently in evidence in a neuropathic anlage. The same picture is seen in those who have not been under fire. These cases are all closely connected with the desire for compensation, just as is the case with victims of traumatic neuroses in peace times. It is curious at least that in Sweden and Denmark, in which there is no motive for “damage grafting,” the damage grafter is as good as nonexistent. In the countries mentioned a compromise system after injury does away with him, and excludes

the “unconscious wish” which leads to unconscious, or perhaps conscious, simulation of disease.

Maté.—Rammstedt in describing Paraguay tea gives a number of unconvincing reasons for writing it maté instead of maté, the latter, he says, being only the French equivalent of what he thinks is the native term matte. The active principle, known as mateine, is chemically related to caffeine and theine. Tea contains ordinary tannin, while coffee and maté contain so-called coffee-tannic acid. “Paraguay tea” demands a thorough investigation, which can be easily brought about because two German firms are at present dealing in the herb and can supply any quantity of material. It is not unlikely that after the war it will come to the fore as a new stimulant without the drawbacks of coffee. Maté has in fact been used freely throughout six-day races without any of the bad effects of coffee (tremor, palpitation). At present the leaves are mixed with twigs, dust, dirt, etc., so that it is only about one-third utilizable. The purest leaves contain 1.3 per cent. mateine (caffeine). By screening objectionable leaves, etc., to get rid of admixtures, products are obtained which yield from 0.49 per cent. to 0.96 per cent. of the alkaloid.

Medical Baronets.—The only instance of a medical man, *quâ* medical man, being raised to the British peerage was the late Lord Lister, but there have been a great many medical baronets. The presidency of either of the Royal Colleges is now considered to carry a baronetcy with it. In the case of the Royal College of Physicians (of London) the first baronet was Sir Hans Sloane, who was president in 1719. Since 1862, all the presidents have been baronets with two exceptions. There are now twenty medical baronets in the United Kingdom. Two medical men have inherited baronetcies, Sir Hugh Beevor, who is the fifth baronet, and Sir John Broadbent, who succeeded his father as second baronet in 1907.—*Medical Press.*

Arsenobenzol in Syphilis.—Tommaso Pontano presents the following advantages of employing arsenobenzol in lues: (a) Syphilitic fever yields to arsenobenzol as malarial fever yields to quinine. (b) In bone syphilis the pains cease in one or two days. (c) Neuropathic syphilitic cases, not of degenerative character, are profoundly and rapidly modified by the arsenobenzol treatment (headache, neuritis, radiculitis, gummata), functional integrity is often restored to the patients with the suppression of the pain; and a state of vertigo, which with a temporary amelioration resists mercurial treatment, may cease in a short time. (d) In febrile gummatus hepatitis, after a useless mercurial treatment, the arsenobenzol treatment may arrest the fever and decide the recovery of the patient. (e) In dyspnea and the pains of aortitis arsenobenzol rapidly causes the pain and dyspnea to disappear, whereas mercury acts slowly and sometimes fails in its object. (f) In syphilitics, moreover, with chronic well-compensated nephritis, the only therapeutic agent well tolerated is arsenobenzol. (g) Iritis and parenchymatous keratitis yield rapidly under the action of arsenobenzol.—*Universal Medical Record.*

Ichthyol in Erysipelas.—Dr. Helen Sexton reports the case of a soldier with a large suppurating wound on the inner side of the arm, in which erysipelas developed, the redness and swelling extending below the elbow. The arm was painted every twelve hours with ichthyol and glycerin equal parts, and covered with oil-silk, and a mixture containing large doses of bichloride of mercury was given. In forty-eight hours the temperature was normal, and all the local symptoms of erysipelas had disappeared; the wound was then dressed with ordinary hypertonic saline solution.—*British Medical Journal.*

Society Reports.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, January 12, 1916.

THE PRESIDENT, DR. E. E. MONTGOMERY, IN THE CHAIR.

THE meeting was devoted to a discussion of the "Important Every-Day Economic and Ethical Problems of the Practitioner of Medicine."

The Problem of Increasing the Physician's Income: What Shall We Do to Be Saved?—DR. THOMAS F. REILLY of New York read this paper. (See page 364).

Ethics of Fees and Fee-Splitting.—DR. JOHN B. ROBERTS of Philadelphia referred to the fact that at the present time graduates in medicine have a choice between following a strictly scientific medical career, a sociological one, or a pedagogic service instead of the mere treating of disease. The last named was the only vocation formerly adopted by physicians. In the three forms of professional life first mentioned there was no question arising as to fees. The laboratory man, the municipal officer, and the college teacher received a definite salary. The ethical point raised in the mind of the therapeutic doctor was how much value should he place upon his services to a sick or injured patient. This, Dr. Roberts believed, must be determined by the quality and duration of attendance and the responsibility assumed by the doctor. The relation, he pointed out, was not a commercial one, but had a professional nature like that of a lawyer or priest. The physician, therefore, must be willing to reduce his charge from that normally asked if the patient were unable to pay the full amount. If the physician were unwilling to do this he should not, in Dr. Roberts' opinion, assume the relation of professional adviser to a man probably unable to pay the full fee. The term, fee-splitting, had been used to describe the giving of a commission by a specialist consulted in a case of disease or injury in the hands of another physician. The term was bad, because it did not include in the title the only point which made the division of fee responsible, namely, the secrecy of the cleavage; the patient's money might be divided among as many doctors as chosen, provided the patient knew who got his money.

Psychology of the Physician as a Wage Earner.—DR. CHARLES W. BURR of Philadelphia announced that he had been somewhat astonished at being told that he was a wage earner. In the simplicity of his innocence he had believed that physicians did not get "wages," but "deigned to accept fees." He did not know that they were mere laborers, who, having been paid their wage, were settled with; but, rather, that they did daily things that could not be paid for, save in a coin with a different sound from the ring of gold or rustle of greenback. In the question given him by the program committee, the psychological difference between the physician as a wage earner and others, as in any psychological study, the factors compelling and controlling conduct were first to be considered. Chance, choice, and destiny, Dr. Burr declared, made men physicians. Excluding the small percentage of men entering medicine from purely altruistic motives, there were, in the author's opinion, five classes: (1) Those not wanting to work with their hands, imagining it to be much easier to work with the mind, and much more respectable; (2) those regarding medicine as a gentlemanly occupation which sometimes enabled one to marry a rich wife; (3) those believing it possible to make money by criminal practices without being caught; (4) those believing they could make money, notwithstanding the general opinion to the contrary; (5) those who, having a hunger for things intellectual, were drunk with scientific inquisitiveness and curious to learn the secrets of that strange machine, the living animal. When destiny agreed with choice there was the student who alone should be encouraged, and of this type Dr. Burr believed there was a sufficient number to meet the demand for physicians. In his opinion, the time was coming when the physician by destiny and choice alone would survive, and at that time there would be no need of discussions upon salvation from being poor. Dr. Burr did not find anything in the physician as a wage earner differentiating him from the rest of the world. He thought about as many physicians proportionately as business men made incomes of \$10,000 a year, which, in the opinion of amateur sociologists, meant success. He did not find the physician more

careless in business matters than other people. There was, however, a psychological answer to the wage question among physicians—that of permitting only those in whom choice and destiny met to study medicine. The few schools of the better class, it was stated, had already taken steps in this direction. When low class schools ceased to exist the wage question would care for itself. Trade-unionism, of which much was heard under other names as the cure-all for professional ills, Dr. Burr did not believe would help; but rather it would hurt, because it would increase the wages of the incompetent and decrease the wages and work of the best.

Safe and Sane Investments for Physicians.—MR. THOMAS S. GATES, president of the Philadelphia Trust Company, made the statement that there was a science of investments just as there was a science of medicine. The medical profession, he said, would view with contempt patent medicine advertisements, yet many of the alluring invitations to invest money were quite as remote from the proper fields of investment as was the patent medicine bottle from the intelligent doctor. Stocks and bonds which were fundamentally most desirable, he said, did not appear in the newspaper. Persons not actively involved in the business of caring for money, he believed, would do well to regard that function as a specialized one, and enter it upon their own account with the same caution with which a banker, for instance, would attempt to give a prescription in medicine. A few cardinal principles, positive and negative, he said, governed the investment of money. Upon the negative side, the mere fact that one had money to invest was no argument for investing it at the moment; ruling prices should be considered. In the temptation to buy a stock rather than a bond there should be remembered the fact that in the buying of stock the purchaser became a partner in the business and consequently should know something of its management and of the industrial conditions surrounding it. Were the temptation that of a mining investment the important point to remember was that a mine was ever consuming itself. The salability of an investment also was not to be overlooked. If in the original purchase the judgment had been at fault it was believed better to face a loss and start over again than to stick to a bad bargain. Upon the positive side it was advised that the busy professional man invested his accumulated earnings to better advantage if he assumed certain fixed charges whereby his savings month by month were placed in the hands of those qualified to make earnings pay. One of the best forms of such investments, he said, was that of life insurance, which, as at present operated under State regulation, gave the protection of savings for after years with a larger payment in case of death. The building and loan associations, also under State control, when well managed, gave the investor a very fair return and an investment upon real estate security which, in the last analysis, was the highest possible form of security. A mortgage upon real estate, Mr. Gates believed, was not a particularly good investment for a doctor, unless the mortgage were in the hands of one able to attend to the condition of the property. The world, it was said, had but for a few generations regarded as legitimate investment in anything other than land. For many centuries the Christian Church proscribed the taking of interest as a moral offense, and the laws of nearly all civilized countries had made it a crime, while the voice of the publicists and ethical writers had been raised against it. The origin of this prejudice was commonly attributed to a passage in Aristotle to the effect that as money did not produce money, nothing more than the principal sum loaned could be equitably claimed. John Calvin deserved the high honor of having first detected the fallacy of this argument by observing that while money did not produce money, that which might be purchased with money, did, wherein was a perfect justification for the payment of interest. In the buying of a bond, which was in reality the lending of money to a corporation, it should be known that the corporation occupied a satisfactory place in the industrial field, that the bond was secured by a first mortgage protected by an adequate sinking fund, did not run for too long a time, and was salable. Business and professional men, successful in making money, it was observed, gave surprisingly little thought to its safe investment; they followed individual hobbies, and lost. The point to be always borne in mind was the difference between money invested or loaned at interest and money embarked in speculation. The rules which obtained in

the making of an investment obtained also in its sale. While a bond may have maintained a certain fixed price for a considerable period, the improper handling of its sale might very greatly decrease its price. In conclusion the author said that to the ordinary person the purchase of stocks offered no investment whatever. There was needed the technique of the professional trader, or the fatuous stroke of luck to obtain success; and upon this point it was observed that the few possessing the gift of winning told the least of how it was done.

Dr. JOHN B. MCALISTER, President of the Pennsylvania State Medical Society, Harrisburg, congratulated the Society upon the choice of the subject under discussion and thought it unfortunate that such matters were not more generally considered in medical societies. Fortunately the time had passed when the physician prided himself upon working hard and living and dying poor.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held November 16, 1915.

Dr. T. STUART HART IN THE CHAIR.

Observations on Forty Cases of Typhoid Fever Arising from a Common Source.—Dr. ORRIN S. WIGHTMAN presented this paper in which he stated that the only way definite conclusions could be reached relative to the methods and treatment of typhoid fever was through the observation of a sufficient number of cases to offer a fairly accurate comparison of results. With this idea in view he had chosen certain factors entering into a recent series of 40 cases of typhoid fever treated at the City Hospital. All of these cases were traced to a common origin, and thus offered a bacillus which could be cultured, and an attenuated vaccine carefully made which offered a reliable method of using vaccine therapy of known dimension, that was, so far as an isolated common infecting agent could be known. Of these 40 cases, 20 were set aside; 10 of these were given vaccine treatment and 10 were used as controls. The vaccines were given in doses varying from thirty-five to one hundred million, usually but one dose being given. The unsensitized vaccine proved dangerous and was promptly discontinued. The serum was at first sensitized from an immune patient, later immunized rabbit serum was used, and, still later, strains of the Army serum were used; these proved most satisfactory of all. An intravenous injection was followed by quite a marked reaction, which usually began to subside at the end of twenty-four hours, though in some cases it took from forty-eight to seventy-two hours. Practically all the cases in which there was a marked fall in temperature within twenty-four hours after the injection lost all the subjective symptoms of the disease, but this was not a true guide as the pulse rate did not reduce in proportion to the temperature chart. Aside from the temperature drop and general feeling of well-being, there seemed to be no limitation of the course of the disease, nor were they less careful in the subsequent management of these cases than of others. Practically all the cases had a severe albuminuria with casts. No rashes accompanied the use of the vaccine. The pulse became rapid and running and respiration in proportion. There was a tendency to marked peristalsis of the intestines with cramps and diarrhea. The marked kidney reaction together with the urinary findings warranted caution in this direction. A second series of experiments was made with reference to dietetics. A series of ten cases was confined to the liquid diet, and a second series of ten cases was given the so-called mixed diet. Feedings in both instances were given in small quantities every two hours, starting at 6 A.M. and continuing until 10 P.M. Those confined to the liquid diet were in much poorer shape at the time of normal temperature range than the mixed feeders, and made a longer convalescence. The caloric value of the food was charted each day, and it was surprising how low a food value was compatible with an uneventful course of the disease. Particular care was accorded the mouths of all the patients, in order that reinfection from this source might be prevented. Dobell's solution was used freely and chewing gum was given several times daily. Rules for the care of the ward and all patients were prominently posted and rigidly enforced. The care thus exercised was fully justified in that there

was no evidence of any infection among the physicians, nurses, or other patients in the hospital.

Dr. ALFRED MEYER asked what was the common source of infection.

Dr. WIGHTMAN replied that under the city administration this was hard to find, but the cases must have come from one of the adjacent islands. In all there were about eight cases sent to the hospital and they got about one-half of them.

Dr. MEYER said that it seemed to him that there was an immense amount of valuable evidence contained in the medical literature of all countries regarding the value of immunization against typhoid fever and that at present the only doubtful point was the duration of the immunity, but that in all probability this was at least two years. In 1914 he sent a questionnaire to forty large hospitals and training schools for nurses in New York inquiring whether nurses, house staff, and administration staff were immunized. The replies indicated that the institutions in New York were behind the times in not acting up to the evidence at hand to limit this disease in institutions. There was practically but one hospital in the City of New York where compulsory vaccination obtained, and that was in Mt. Sinai Hospital. In a very small number of institutions only volunteers were immunized.

A Case of Extreme Hematemesis; Transfusion Three Times.—Drs. R. F. DONALDSON and C. N. B. CAMAC reported this case. Dr. Donaldson presented the patient, a girl nineteen years of age, and stated that the case presented several points of interest worthy of mention. Her history was unimportant except for frequent attacks of tonsillitis in childhood and an attack of what was apparently acute infectious arthritis, when she was thirteen years of age. On January 15, 1914, the patient, seemingly in good health, save for a vague epigastric distress, vomited about a pint of pure, dark-red, unclotted blood. This was repeated on January 17 and again on January 20, when she was admitted to the City Hospital suffering from a grave anemia. Physical examination was otherwise negative except for a rough systolic mitral murmur well transmitted to the axilla. On the following morning the patient had three more attacks of vomiting, which caused the loss of thirteen ounces of blood. The blood picture at this time showed 1,800,000 red blood cells, with 22 per cent. hemoglobin. There was slight polychromatophilia and two normoblasts were found after twenty minutes' search. Dr. Camac's notes at this time showed that the patient's lips bled readily and were crusted; the pupils were small, conjunctivæ pearly white; pulse regular and about 120, full but not forcible; visible pulsation of the vessels of the neck; slight thyroid fulness; no intrinsic thyroid pulsations. There was a visible precordial impulse, which was diffuse and found by palpation in the fourth interspace, just outside the midclavicular line, four inches from the median line. At the point of maximum impulse a loud first sound associated with a murmurous element, which was heard in the axilla, also was noted. There was a softish systolic murmur differing in quality from that of the precordial midclavicular impulse heard at the body of the heart, over and to the right of the sternum. The percussion note over the lungs anteriorly was resonant. There was no excess of adipose tissue on the abdomen, but the costal margins were obliterated. The lesser curvature of the stomach began at the upper border of the fifth rib. The tympanic note extended to the costal margin, where it was replaced by a flattish note, tympany returning at the level of the umbilicus. Liver dulness was replaced by a tympanic note, which was continuous with that of Traube's space. There was no venous prominence over the chest or abdomen. A direct vein to vein transfusion from her twin brother was successfully performed by Dr. Harry Janeway. It was followed in two hours by a profuse menstrual discharge which was more or less continuous for the next eight days. Five hours after the transfusion the patient was given 55 c.c. of horse serum intravenously. This was followed in a few hours by her seventh and last hematemesis. On the following day a second transfusion with a different donor was successfully performed. There was slight hemolysis and agglutination with the cells of the donor. A hemoglobinuria of seventy-two hours' duration followed this transfusion, when a third transfusion from a previously tested good donor was performed and this improved the patient's condition markedly. From this time on she steadily improved, until April 14, 1914, when she was discharged from the hospital. She had en-

joyed good health since that time. Recovery in this case seemed to be due in a large measure to the three transfusions. The method used, the direct vein-to-vein transfusion, would probably at the present time be supplanted by the indirect method with citrated blood. Their experience with the latter at the City Hospital had shown the technique to be exceedingly simple, and carefully controlled cases had shown only a very slight decrease in coagulability three-quarters of an hour after transfusion, and a definite increase in coagulability one hour and a half later. This case was interesting because it showed the possibility of recovery even in the presence of almost exsanguinating hematemesis, and because of the marked improvement following the transfusions.

Dr. LEWISOHN said that he was much interested in the subject of the increased coagulability of the blood after citrate transfusion; if citrated blood was transfused into a patient, the time of coagulability of the blood was shortened. Shortening the coagulation time by the citrate method in certain conditions offered a great advantage over other methods of transfusion, especially in hemophilia, purpura, etc. The only proper test for coagulation time was to introduce the needle in the vein of the patient and to take a test every one-half an hour, but the method was not easily applied. He had tried it in two patients and he found the coagulation time, shortened in the beginning, returned to normal in twelve hours. It seemed that there must be an over-production of prothrombin after injection of the citrated blood. The coagulation time was normal again after twenty-four hours. So far as the clinical application of the citrated method was concerned, he had seen about fifty cases of transfusion performed by this method. One great advantage was its simplicity.

Dr. MOSCHCOWITZ said that during February he was called upon to operate upon four cases of unequivocal ulcer of the stomach, but at operation no ulcer was found. In many of these cases of severe and profuse hemorrhage the victims might die, of course, but it seemed to him that the deaths were due, not to ulcer of the stomach, but to erosions of this organ.

Dr. HENRY ILLOWAY said that the case reported by Drs. Donaldson and Camac was certainly a most interesting one. In the consideration of the question as to the cause of the hemorrhage it was possible, as had already been said, that a large erosion of the gastric mucous membrane might have suddenly occurred, as it was held that an anemic condition favored the development of ulcer ventriculi, and this girl, the reporters said, was markedly anemic. However, the subsequent history of the case, the fact that she could eat well, ate the food given to hospital patients shortly after the arrest of the hemorrhages, spoke very strongly against such an assumption. The hematemesis might have resulted from the rupture of a small aneurysm in the stomach and such a case had been reported. It must also be remembered that varices, small aneurysms, of the esophagus located mostly near the cardia, where the esophagus ended, and there was a transition of tissues, might be the source of very severe hematemesis. It was a question whether the hemorrhages might not have been due to the condition of the blood, analogous to what they saw in scurvy. According to the description given of the patient such an assumption would not be at all far fetched.

Dr. JOSHUA M. VAN COTT said that he was very much interested in the condition of the teeth and their possible relation to the mitral lesion in this case. It was suggestive of infection of an embolism from the mitral valve, involving a deep branch of the gastric artery. Years ago he saw a somewhat similar case at the New York Hospital when the late Dr. Frank Ferguson was the pathologist there. A young girl died of repeated attacks of hematemesis and the autopsy revealed a very small ulcer of the stomach which had bitten the gastric artery.

Dr. DONALDSON said that in this case when the teeth had to be extracted no pus was found at the roots.

Some Clinical Observations on Battle Shock.—Dr. FOSTER KENNEDY said that he had seen many cases which had been described as suffering from "bullet shock." They differ from those instances seen in civil life only in degree. It was astounding that in the first line trenches there was so little grave mental or nervous disturbances, and it was only under the greatest physical stress that there followed a mental breakdown. It was seldom fear that knocked these people out; it was usually a lack of sleep. If a man was well fed and got five out of twenty-four hours for sleep, he was usually

able to avoid that collapse in which he would laugh or cry and had to be taken away. Dr. Kennedy said he had seen a fairly large number of paraplegias and the like, especially after a heavy shell had exploded in the neighborhood of the men. He saw one man stripped naked, with his clothing in strips, who had not a single wound. He related an interesting case of a child of ten years who was with the family at their mid-day meal when a shell fell in the middle of the room. This little girl was in the corner of the room stirring soup. The bursting shell obliterated the house and killed the people in the house except the little girl, and the part of the room in which she was standing was left intact. Her mental processes stopped abruptly at the moment of the explosion of the shell and her life was held up. Dr. Kennedy did not believe there was any especial form of insanity developed by war, but the more feeble minded persons would break down under the stress imposed upon them. On the other hand, it was true that civilians who were asthenic, hesitating, and feeble in time of peace became frequently astute and strong members of society in war, succeeding in mobilizing their reserve forces to meet the extraordinary demands put upon them.

An Unusual Atypical Case of Pulmonary Osteoarthropathy.—Dr. HARLOW BROOKS reported this case. He stated that the patient was an Austrian by birth, twenty-eight years of age. His family history was negative except that he asserted that his father and his own son, a child of five or six years, presented physical peculiarities similar to his own. In so far as the child was concerned, however, this statement was disproven, for while the child resembled the patient it was in none of the deformities which characterized the case. The patient used alcohol moderately, denied history of venereal disease, and the Wassermann reaction and complement fixation test for gonorrhea were both negative. His wife had borne two healthy children and had had no miscarriages. The patient was stupid mentally, slow in thought, and the details of his history were probably not trustworthy. His present illness started three months before his admission to the hospital with severe headaches, heavy night sweats, and a persistent headache. During this time he had coughed a great deal and raised much sputum, but he did not attach much significance to this symptom since he said that he was accustomed to the cough, which he did not mind so much as the severe pains in the legs, back, arms, and particularly in the wrists. The patient presented in the gross the picture of a powerful, well-muscled male. The most striking peculiarities were shown in the head, the frontal eminences being very large, the face marked by very heavy supraorbital arches and by heavy loose movable masses of semi-cartilaginous consistency situated symmetrically at the outer angle of each eye. The zygomatic arches and malar prominences were very large and palpation indicated a thickening of the periosteal and subcutaneous connective tissue. Firm pressure caused pain. Some nodules of almost bony solidity were present in the subcutaneous connective tissue. The lateral nasal bones were also much thickened and tender; true bony formation was apparently taking place here. The end of the nose was globular, cyanosed, usually cold, and apparently the site of fibrous growth. The thorax was well formed, but the respiratory excursion was narrow and the lateral view showed a tendency to the stoop characteristic in acromegalia. Although the extremities in general were shapely and well muscled, the wrists and ankles were notably large and tender on pressure or manipulation. The bone borders felt nodular and infiltrated. The fingers were typically "sausage shaped." The toes were slightly clubbed. The movements of the hands and feet were definitely impeded, as though from the thickened skin. Occasional atrophic areas of skin also appeared over the entire body. A thorough physical examination gave negative results in all other respects. The patient's pains were relieved under restricted diet, rest in bed, salicylate of sodium and sodium bicarbonate. At the time of his discharge the diagnosis lay between acromegalia leontiasis ossa and possibly an obscure type of osteoarthropathy. The patient reported from time to time and finally came with very definite chest symptoms, diffuse bronchitis, flattened percussion note over the entire chest, numerous râles, abundant purulent sputum, and the typical swelling and tenderness of the periosteum in the usual location. This development confirmed the diagnosis of pulmonary osteoarthropathy.

Dr. GEORGE B. WALLACE asked if there was any ele-

ment of myxedema in the case which had been reported.

Dr. BROOKS said that they had tried the thyroid treatment but to the detriment of the patient.

Dr. ALFRED MEYER said that some of the photographs circulated showed a marked retraction of both apices. He asked whether inoculation of guinea pigs with sputum had been practised to determine the presence of tuberculosis.

Dr. BROOKS replied in the negative.

The Diagnostic Importance of the Estimation of Uric Acid in the Blood in Cases of Chronic Arthritis.—Dr. JOHN CARROLL read this paper, in which he reported the results of a part of a study begun in cooperation with the staff of the Strecker Memorial Laboratory and having for its object the better classification of chronic arthritides, based on a combined chemical, bacteriological, and clinical analysis. After citing the many factors that presented difficulties when one attempted to draw conclusions from the amount of uric acid appearing in the urine, the essayist reviewed the conclusions of Folin and Denis in a recent article which were as follows: 1. In gout the blood was almost invariably high in uric acid while the non-protein nitrogen was usually within normal limits. In arthritis the blood not infrequently was high in uric acid, but most such cases had abnormally high non-protein nitrogen as well. 2. Neither qualitative tests for uric acid in the blood nor quantitative determination of uric acid alone could be depended upon in a differential diagnosis in gout or other arthritides. 3. For differential diagnosis in gout or arthritis by means of blood analysis the patient must be put on a purin-free diet and the uric acid determination must be accompanied by the determination of non-protein nitrogen. In the present study all medication was withheld for two weeks and a purin-free diet was instituted for five days before the specimens for analysis were taken. In 27 cases thus studied, 13 had abnormally high uric acid concentration, all being above 3.3 mg. per 100 c.c. In 10 cases the uric acid was below 2.1 mg. per 100 c.c., and four cases had uric acid above 2.7 and below 3.3. Of the 13 cases with high uric acid, 12 were cases of gout, and one was of sufficient importance to justify reporting in detail. This patient was a male, 34 years of age, who was admitted to a New York hospital ten years ago suffering with an acute gastrointestinal illness. There was repeated vomiting of blood, and a diagnosis of duodenal ulcer was made. The patient at this time noticed pain in the joint of the middle finger of the right hand. After this time his history had been one of a slow continued succession of joint involvements up to the present time. He now presented the classical picture of arthritis deformans. Five years ago he had an acute attack of diffuse nephritis. His admission to the City Hospital had been for an acute attack presenting the picture of gastroduodenal ulcer. This was one of the three cases in the series in which the rest nitrogen in the blood was above the normal figures, being 59 mg. per 100 c.c., and this and the high uric acid concentration (6.4 mg.) could be explained by the concomitant nephritis. The 11 cases with low uric acid were the types classified under arthritis deformans, four being of the pure atrophic type; four of the periarticular type, with a doughy swelling of the periarticular tissue without much deformity, with a moderate degree of temperature, a moderate leucocytosis, and a general glandular enlargement; three were classified as a chronic arthritis associated with and due to intense pyorrhea, marked anemia, moderate temperature, great deformity, exquisite pain, and mobilization of the joints, with moderately high uric acid. The borderline cases had a blood urea above 2.7 mg. per 100 c.c. and below 3.3. Two were definite cases of gout in which the crystals were demonstrated, and two were cases of spondylitis deformans. A high filtrate nitrogen was present in three cases, one being the case cited in detail, and the other two were in definite gout cases in which a coincident cardiac decompensation existed. From the analysis of these cases the essayist stated that he felt justified in drawing the following conclusions: (1) That in gout the blood was almost invariably abnormally high in uric acid, while in non-protein nitrogen it was usually within normal limits. (2) That in non-gouty arthritis the uric acid was usually low. (3) That the non-protein nitrogen, when above normal in either gout or arthritis, could usually be accounted for in recognized associated conditions that cause it, such as increased catabolic or fever-cardiac decompensation and nephritis. (4) That for a differential diagnosis in doubtful cases of gout or arthritis, the specific medica-

tion must be withheld for at least a week or ten days and the patient kept on a purin-free diet for at least five days.

The Use of Bichloride of Mercury as a Substitute for Salvarsan in Intraspinous Injections.—Dr. LIVINGSTON HUNT read this paper, in which he called attention to some of the work that was being done in neurology at the City Hospital. He said it was not an effort to introduce a new therapeutic measure nor to disparage an old one, but rather a record of work done. The war had made salvarsan so difficult to obtain, and its price was so prohibitive, that they had been obliged to seek other means in the treatment of syphilis of the nervous system. Accordingly last summer they had tried the intraspinal administration of mercury. He stated that his paper was only a preliminary report on 45 cases, 40 of which were given intraspinal injections of bichloride of mercury, and five were given sublimine injections. In all 100 injections of bichloride of mercury and 33 injections of sublimine (mercury-ethylene-diamene sulphide) were given. These cases at the same time were given every week intramuscular injections of salicylate of mercury and in the very early ones intravenous injections of salvarsan. The cases treated comprised cases of tabes, general paresis, cerebrospinal syphilis, tabo-paresis, clinical tabes, that was tabes with a negative serology, and syphilitic hemiplegia. The intraspinal injection of mercury was made in the following way: About 50 c.c. of blood was obtained from the patient's arm with a needle of large caliber, and collected in a sterile cylinder, preferably four hours after an intravenous injection of salvarsan. The blood was slanted, the clot separated, and then left over night in the ice-box. The next morning a sterile centrifuge tube, containing about 13 c.c., was readily filled with clear serum, and was then centrifuged for five minutes. A few red blood cells were collected at the bottom of the tube, and the supernatant fluid was poured into a sterile, freshly washed cylinder. To this one-fiftieth of a grain of bichloride of mercury was added.

The mercury was prepared by taking one gram of bichloride of mercury, very carefully weighed, and adding it to a liter of sterile distilled water, which was then brought to the boiling point. The bichloride would then completely dissolve and 1.3 c.c. of this solution contained approximately one-fiftieth of a grain of bichloride. The mixture was then made up to 30 c.c. with sterile saline, and inactivated for a half an hour at 58° C. It was then injected within an hour. The injection was given with the patient lying on his side. A 30 c.c. syringe was used and the fluid run in by gravity alone. The foot of the bed was elevated for an hour after the injection, and phenacetine was used liberally for the pain. After analyzing the cases somewhat more in detail Dr. Hunt summarized the forty-five cases as follows: Six cases showed marked subjective improvement as regards the general conditions; nine showed marked subjective improvement; twelve showed some improvement subjectively, but it was slight; thirteen showed no improvement; two became worse, and three died. In seventeen of the cases there was a well-marked reduction in the cell count and globulin, the Wassermann reaction not being readily changed. The author reported seven cases in which he had been able to follow the history closely from the beginning of the treatment to the present moment, together with the physical and laboratory findings. He concluded as follows: (1) The reaction from bichloride of mercury or sublimine in no way differed from the reaction which followed the administration of salvarsan. (2) The sublimine did not seem to give the same reduction in the cell count or clinical improvement as did the bichloride. (3) No ill effects followed these injections. The three deaths could be easily accounted for as the patients were practically moribund at the time of treatment, and were given the injections as a last resort. (4) The cases of tabes and cerebrospinal syphilis were helped more than any others. (5) Such improvement as did occur was evident in the feelings of the patient, in the sphincter control, in the pains, the gait, and the serology. There was no improvement in the reflexes. (6) Such intraspinal treatment could only be given at intervals of two weeks, because a cell count did not fall sooner. (7) The reaction obtained was one in which the cell count was first greatly increased and diminished only later. (8) The cell count and the globulin yielded much sooner than did the Wassermann reaction.

Stated Meeting, Held December 21, 1915.

DR. T. STUART HART IN THE CHAIR.

Causes of Death in Diabetes.—Dr. ELLIOTT P. JOSLIN of Boston said that he believed that the life of a diabetic patient might be prolonged, and that coma was an avoidable accident. The results of investigations with Professor Benedict at the Carnegie Laboratory and also observations at the Russell Sage Laboratory strengthened him in this belief. Also, the fact that under simple fasting treatment no death from diabetes occurred at the New England Deaconess Hospital for 350 days, confirmed this belief. During the past 21 years, 17 deaths from diabetes had occurred under his supervision in hospitals, and the rest outside. In order to avoid enthusiasm, Dr. Joslin said he had ascertained the causes of 98 per cent. of the deaths of diabetic patients seen by him since 1894. Of that number, 421, 152 died without coma. Of those, there were 13 miscellaneous deaths, 15 due to cancer, 16 due to tuberculosis, 32 to infections, and 56 to cardiorenal and vascular trouble. It would appear probable that if the methods employed in the treatment of these same arteriosclerotic conditions in non-diabetic patients were carried out, these methods would work well with the diabetics. An infection was an additional load for the diabetic to carry, and to it he often succumbed. The advantage of treatment of infections of the leg, recommended by Dr. Slettin in the *Journal of the American Medical Association*, 1913, Vol. 60, p. 1126, was emphasized. Several of the tuberculous cases had done very well. The bad prognosis formerly given was probably due to the patient's coming late for treatment. The cause responsible for most of the deaths was coma. Upon studying these cases it was evident that the predisposing cause was etherization in quite a group of cases. Ether anesthesia was a burden which a light case of diabetes might bear easily, but which might change a moderate case to a severe one, and a severe case might be fatal. Impaired kidneys which were unable to excrete the acids formed were a second predisposing cause; third, infections, both local and general; fourth, and this is by far the largest group, a rapid change to a fat-protein diet. This was the culminating factor in many long-standing cases of diabetes. Fifth, a rapid loss of fluid due to decrease in salt in the diet appeared to have caused coma in one instance. Coma in a diabetic patient was like the perforation of a duodenal ulcer in a dyspeptic; the catastrophe was not of recent origin. In severe, long-standing, and complicated cases, Dr. Joslin said he had prepared patients for fasting by omitting fat for two days, then omitting protein, and upon subsequent days halving the carbohydrate until only 10 grams of carbohydrate were given, and upon the following day fasting treatment was taken up. Upon the first days of fasting one should give broths. Otherwise the patient would lose weight because of lack of salt in the diet. Since September 24, 1915, no sodium bicarbonate had been given a diabetic patient either in or outside the hospital, and yet acidosis had been controlled. A chart of fatal and living cases showing the duration of life for each decade was shown, and in each decade except the sixth and seventh, the living cases, despite the fact that this number included those recently coming for treatment, showed a duration of life considerably greater than that of the fatal cases. This was good evidence that the treatment of diabetes was improving.

The Treatment of Diabetes, with Especial Reference to Acidosis.—Dr. EDGAR STILLMAN of the Rockefeller Hospital said that the object of the fasting treatment of diabetes mellitus was not only to render the patient permanently aglycosuric, but to control acidosis. After glycosuria, acidosis was the most dominant factor in the treatment. The term acidosis signified the accumulation of acid bodies in the blood and tissues sufficient to neutralize enough of the sodium bicarbonate there present to reduce the alkaline reserve to a level below normal; it did not mean an actual acid reaction of the blood and tissues. Urinary tests for acidosis were often misleading in that they were indicative merely of the excretion of acid bodies and were not a true index of the actual accumulation. On the other hand, an analysis of the blood sodium bicarbonate by the Van Slyke method offered an accurate measure of the accumulation of these bodies and gave a true index of the degree of acidosis present. Diabetes might be classified into four groups according to their response to fasting. It was necessary to bear in mind that each

group should be treated individually, indicated by the degree of acid intoxication measured in degree of blood alkalinity. With a knowledge of the degree of acidosis, determined by the method described, almost all cases of diabetes might be treated by the fasting method safely and with benefit.

The Relation of Prognostic Factors to Treatment in Diabetes.—Dr. NELLIS B. FOSTER said that those factors which influenced prognosis were not habitually considered as intimately related to the problem of therapeutics because of the custom of thinking in the terms of acute disease, though the necessity of doing so was self-evident. When a man suffering from chronic renal disease was advised to seek a mild winter climate, the physician was trying to avoid the danger of pneumonia to his patient, thus considering a prognostic factor as a problem in preventive therapeutics. Chronic disease was the cause of death in only a minority; the majority, weakened and undermined in health, died of acute superimposed infections, or of complications. It was necessary in each case of diabetes to form a clear estimate of the dangers which menaced the individual patient in order to carry out the prime endeavor of prolonging life, and it was no less requisite to consider these factors in the means adopted to ameliorate the symptoms of the disease. Infections took first rank among the dangers which beset the diabetic and accounted, by precipitating coma, for over 78 per cent. of the deaths. Since this danger, which killed the majority of diabetics, menaced all alike, any mode of treatment which disregarded these prognostic factors was lacking in foresight. The disease once contracted, the only safety was in keeping the patient in some condition approximating to normal vigor so that infective agents found a less fertile soil. Disregard of one ultimate aim of therapy in diabetes, that was, an approach toward a healthy state of resistance to infectious disease, so often led to calamity that he was frankly pessimistic for that group of cases which could attain and preserve a sugar-free urine only at the expense of nutrition. The average diabetic not only had more comfort and sense of well-being when his urine contained no sugar, but his actual resistance to infection was higher. There were cases in middle life where a severe glycosuria was not complicated by acidosis and where under-nutrition and loss of strength were the striking features; most of these cases regained strength and energy after the glycosuria was controlled. With others, the diet which controlled the glycosuria, necessitated that the patient remain some 20 per cent. under normal weight; while with a diet that held him but 10 per cent. under weight he had less than 15 grams of sugar daily in the urine. It was doubtful which was preferable. Again, exercise benefited the majority of diabetes, but some patients had slight rises in temperature after exercise though without the exercise the tolerance for sugar was too low for safety. These questions were intimately concerned with the future of the patient and were best decided by remembering from what direction danger approached. The real criterion of success in treatment was not the fact that the urine did not contain glucose, but the percentage of blood sugar. To excessive hyperglycemia was to be assigned a large degree of impairment of function; the tolerance appeared *nil*, but after a few months' treatment when the blood-sugar was reduced to only a little over normal there was often a surprising ability to use carbohydrates. It was impossible to tell in advance whether any given case was mild or severe; many that seemed severe in the beginning, even with considerable acidosis, proved after a year to be only mild; but this was true only when the disease was not of long duration. Dr. Foster said he divided his cases into two groups: early and advanced. The severity of the acidosis or glycosuria in the beginning was no criterion of the actual condition and this was demonstrated by cases that were infused at the beginning of treatment because of incipient coma. The history of these cases indicated about a year's duration of the diabetes, and some of them were now using on five days of the week unrestricted amounts of starch without resultant glycosuria; one of them had normal blood-sugar unless the routine vegetable day was omitted for several weeks. All were under thirty-five and all up to normal in weight and vigor. These cases illustrated the difficulty in differentiating mild from severe diabetes. Concerning the cases of young adults who were observed first when the disease was of some years' duration, the advanced cases, the results had not been encouraging even when, on account of slight acidosis, it appeared in the begin-

ning that the task was much easier than with the early cases. The glycosuria might be easily controlled, but the blood-sugar was difficult to reduce to normal; it remained normal only under the most restricted conditions and, as a rule, the tolerance was too meager to preserve health over long periods. To this group belonged those patients who had adhered to diet and died of complications and infections wherein coma occurred only as a sequel to acute disease. Of those who had not been so rigidly dieted, the majority had died in coma. The period of life in both groups averaged over two years from the beginning of treatment. The point was that with advanced cases in young persons the results were often discouraging even when the disease was apparently under control. With early cases much could be expected from treatment; vigilant control of the diet so that glycosuria was absent and the blood-sugar down to nearly normal was justified since with time tolerance increased, and even a dangerous degree of acidosis did not necessarily frustrate this design, since it could be abolished. With early diagnosis in some young adults with severe diabetes and considerable acidosis much could be accomplished by vigorous treatment, the end to be attained being a sugar-free urine, blood-sugar as near normal as possible, and absence of acidosis. The chief danger lay in the after period when because the urine was so persistently normal the necessity of the diet seemed doubtful and restrictions were too often abandoned with consequences that were sometimes serious. The therapeutics endeavors in young patients, in whom the disease was early or advanced, were directed to prevent the development of acidosis or to abolish it after development. If there was no acidosis, it was not necessary to resort to fast-days as a means of controlling the most extreme glycosuria, although this could be attained most rapidly by the complete withdrawal of food, but this was not always safe as starvation induced acidosis. Where acidosis dominated the picture and the disease was of long duration, the menace was coma and the fact that any of the patients could be relieved of their danger, even for a brief time, by fasting was a remarkable contribution to the knowledge of diabetes, and this was the special field for the fasting method which should be used only when other and less drastic methods were inadequate to effect the desired result and only in well equipped hospitals where acidosis, induced by fasting, could be measured, and treatment regulated to meet the new menace.

Dr. FREDERICK M. ALLEN of the Rockefeller Hospital said that deaths under the fasting treatment seemed to occur under three conditions: First, in the patients in whom the glycosuria did not clear up on fasting and in whom death had sometimes seemed unavoidable; but a case recently observed by Dr. Geyelin might indicate that even this type of patients might be saved under sufficiently careful treatment. Second, in those other unusual patients who developed acidosis on fasting, and died because the warning symptoms were not recognized in time by the attending physician. It was to be hoped that the use of the Van Slyke apparatus would give adequate notice of danger in such cases. Third, in those who cleared up as usual on fasting, but who were then placed on diet which allowed glycosuria to return; the glycosuria was again stopped by fasting, glycosuria again brought back by diet, and so on until the patient was practically starved to death. The duty of the physician consisted not merely in fasting the patient sugar-free, but also in devising a diet which sufficed to nourish him permanently without bringing back the sugar. Many physicians would like to have general directions for the diet of patients, with recipes and food lists for each meal. These had not been published and were possible only to a very limited extent. The great essential was that physicians should recognize the need for individualizing the treatment for every case. The diet of every patient had to be worked out to suit his tolerance for carbohydrate, for protein, and for fat; these were added in small portions, day by day, according to some method to show the tolerance for each. The treatment was like that of a heart case—first absolute rest and then putting on strain very gradually and cautiously. A few hours' study would enable any physician to order foods according to their composition; he should order them on this basis and not from set diet-lists and should not undertake to treat diabetes unless equipped with this information. Some patients needed carbohydrate first, especially when there was acidosis; some needed protein first, especially when they were very weak; none

needed fat first, and the previous attempts to introduce large quantities of fats on so-called fast-days and vegetable days had been a mistake and responsible for much of the bad prognosis. The second feature in the treatment was exercise. It was always possible that some injurious effect might be observed, but as yet there had been no febrile elevation of temperature, nor any sign of harmful influence in any case. Beginning gradually, when the patient was weak, the exercise was increased to make an athlete of him as far as possible. Severe diabetics had reached the point where they walked several miles a day, went roller skating, jumped rope, climbed stairs, threw the medicine ball, and spent most of their day in muscular exercise. Aside from the slight rise of tolerance, the benefit consisted in abolishing insomnia and neurasthenia and building up the patient's general vigor and resistance. The differences between this method and previous methods of treatment might be grouped into the radical differences and the differences of degree, or detail. The radical differences were: first, the long fast and the demonstration that this cleared up glycosuria and acidosis in cases of the most desperate type. Magnus Levy had emphasized the fact that the only known method of warding off coma had been the neutralization and elimination of acetone bodies by means of alkali; he pointed out that the ideal treatment for coma would be some way of causing the acetone substances to be burned, but that no such method was then known. The fasting treatment did cause the acetone bodies to be burned. The second radical difference was the discontinuance of the use of maximal quantities of fat, and the demonstration that severe cases required limitation of fat and calories as well as of carbohydrate and protein. This was the reverse of the previous method which aimed to introduce fat as abundantly as possible. The other group of differences, namely, those of degree, or of method, were not without importance, and might be decisive in many cases. Among these might be mentioned, first, the shorter time required, since many patients could stay only a limited time in the hospital; second, the principle of requiring permanent sugar and acid freedom in all cases; third, the reduction of weight to any point that might be necessary to achieve these ideals, this reduction often being considerably greater than practised by the Naunyn school; fourth, the education in eating simple foods free from artificial flavors or inducements to overeating; fifth, the use of routine fast-days, even when patients were not showing sugar with the idea of bringing them farther and farther away from the point of showing sugar; sixth, the training of patients in the testing of their urine and other details of treatment, so that they could carry it out intelligently at home. The prognosis could be learned only by further experience. Thus far, results had seemed to justify the belief that diabetes ordinarily was not an inherently progressive condition, but rather the simple weakness of a metabolic function. No patient who had followed the treatment faithfully had died thus far, except one who died of tuberculosis; also, none had reentered the hospital in worse condition than on his first admission. From the standpoint of the diabetes alone, it would probably be conceded that patients would do better when glycosuria and acidosis were kept absent. This left merely the question of their general health and resistance under this program. It was believed that this was the proper treatment, not only for coma, but also for infections. No complication had occurred in any treated patient. Those coming in with carbuncle, gangrene, and other infections had seemed to do better under fasting treatment than before this was instituted. One patient had survived pneumonia. At the Rockefeller Hospital there had been more colds this winter among others than among diabetic patients. It was believed that the resistance of patients was higher when they were kept free from glycosuria and acidosis than when these were allowed to continue, and exercise and fresh air raised this resistance to what seemed a higher level than could ordinarily be attained with diabetic patients. The gain in weight and tolerance with many patients, even with high blood-sugar, seemed to indicate that overstrain was successfully avoided. The question of inherent downward tendency could never be settled by these cases of utmost severity since keeping them alive at all might involve some overstrain and a final fatal result. It was believed that this treatment would at least assure the greatest possible comfort, usefulness, and duration of life even for these cases, and that the efficient application of these principles to the great mass

of mild or moderate cases would save such patients from further downward progress.

Dr. H. RAWLE GEYELIN said that, before going into the account of one particularly interesting case at the Presbyterian Hospital, he would like to emphasize one point that Dr. Allen brought out which he himself had seen illustrated at the Presbyterian Hospital and also at the Vanderbilt Clinic; this was that after these patients were sugar-free on the Allen treatment of fasting, a general line of diet could not be prescribed applicable to each and every case; one had to feel one's way and try out first carbohydrates, then proteins, and lastly fats; also by increasing one food constituent out of proportion to the original individual tolerance. This was very important. Two or three cases which he had seen lately could stand 50 grams of carbohydrates alone before showing sugar, but would not stand 10 grams of carbohydrates where only 20 grams of protein were given in addition. The case he spoke of originally, which was particularly severe, showed sugar on 20 grams of protein alone. The patient was a boy, 19 years of age, who had had an extremely acute history with an onset of three weeks' duration before admission to the hospital and a loss of weight amounting to 40 pounds in this short time. When he came to the hospital he had 90 grams of sugar in a 24-hour specimen and was on the verge of coma with typical air-hunger respiration and all symptoms very suggestive. There was a large amount of beta-oxybutyric acid in the urine—50-60 grams. He had then been fasting for 36 hours and the week previously had been on restricted carbohydrate diet. When the patient was admitted, there was a distinct lowering of the carbon dioxide tension in blood and alveolar air which was regarded at the time as one of the most serious indications so that there was some question as to continuing the fast. This was done, however, and at the end of a five-day fast the patient had been excreting every day between 70 and 80 grams of sugar and there was an excretion of urinary nitrogen ranging to 35 grams, this output being tremendous when it was considered that the patient was fasting. At the end of the five-day fast he had been showing a distinctly decreasing carbon dioxide tension of the plasma and seemed to show less acidosis. On the third day of the fast he showed very marked air-hunger and began to show very great distaste for his carbohydrates; this increased to nausea. At the end of five days, as he showed a large amount of nitrogen in the urine and a correspondingly large amount of sugar, it was determined to feed him, beginning with pure carbohydrate; but the only thing he could take was milk, so it was necessary to resort to protein-fat-carbohydrate diet. After a day's feeding he showed rather distinct signs of improvement and he was then able to be transferred to Cornell for calorimetric study. He was fed for three days before being transferred. At Cornell he was put on a mixed diet, chiefly protein, for 24 hours; then the protein was kept high. He was still excreting large amounts of sugar and nitrogen so that at the end of the second 24 hour period he showed D:N ratio of 3.8, which was very high. At the end of three days' feeding and study of the effect on his metabolism, he was put on a fast. His clinical symptoms had improved before this fast and the carbon dioxide of the plasma went from 19 to .55, this, of course, being accompanied by an intake of large amounts of bicarbonate. He had improved in the last two fast days so that his sugar was less than half in the urine and the urine-nitrogen had fallen to 16 grams. So that the case which had seemed to be absolutely doomed now looked as if there was a very good chance for recovery. The interesting point was that the second fast had seemed to do the patient good, whereas the first one absolutely did harm, and the administration of a protein-fat-carbohydrate diet followed by a pure protein diet was accompanied by a general improvement.

Dr. GRAHAM LUSK urged that the D:N ratio be taken into consideration in the diagnosis of the intensity of diabetes. He referred to the case of Dr. Geyelin which had been investigated by Dr. Du Bois at Bellevue Hospital. The patient when given a meat and fat diet containing 16 grams of nitrogen, eliminated 36 grams of nitrogen in the urine and showed a D:N ratio of 3.8. On the third day of starvation the D:N ratio was reduced to 2.8, indicating that some of the sugar derived from protein during the fast was being oxidized. In a severe case it seemed that the procedure which involved the determination of the D:N ratio might be of significance in diagnosis.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

CALIFORNIA STATE BOARD OF MEDICAL EXAMINERS.

San Francisco, June 15-16, 1915.

(Concluded from page 310.)

GENERAL MEDICINE

1. Typhoid fever: (a) etiology; (b) symptomatology; (c) pathology; (d) diagnosis.
2. In a case of general anasarca, how would you proceed to determine the underlying cause?
3. What are the early signs of tuberculosis, both subjective and objective.
- (b) Describe two important tests for tuberculosis and give relative value.
4. (a) Differentiate acute cerebrospinal meningitis and acute anterior poliomyelitis. (b) Give treatment of the latter.
5. (a) Describe and give management of a case of persistent gastroenteritis in an infant on artificial diet.
6. Give ten causes of headache, and indicate location of pain in each variety.
7. Give a brief discussion of epilepsy, and give general advice to such patient.
8. What is the significance of a blood pressure of 240 in a woman 60 years of age?
9. Give symptoms and treatment of chlorosis.
10. Discuss the various types of asthma from etiologic standpoint, and give general management of one type.
11. Discuss the complications and sequelæ of scarlet fever.
12. What is the usual type of pneumonia in the child; in the adult; in the aged? (b) Give description and treatment of one type of pneumonia.

OBSTETRICS AND GYNECOLOGY

1. What is a blue baby? Give pathology and treatment of the condition.
2. Ophthalmia neonatorum: Give etiology, pathology and treatment.
3. (a) What are the indications for the use of forceps? (b) for cesarean section?
4. Diagnose tubal pregnancy before rupture.
5. Describe the mechanism of labor with a left mento-anterior position.
6. Differentiate polyhydramnios from twin pregnancy.
7. Name the ligaments of the uterus and give the origin and insertion of each.
8. Define and give etiology and pathology of cystocele, rectocele, hematocele and procidentia.
9. Describe an operation for complete laceration of the perineum.
10. Give diagnosis and treatment of pelvic abscess.
11. Give cause, symptoms and treatment of subinvolution of the uterus.
12. Erosion of the cervix: Give cause and treatment.

SURGERY

1. (a) What conditions will cause bleeding from the stomach? (b) State briefly etiology, symptomatology, clinical and laboratory findings, and prognosis of gastric ulcer.
2. What symptoms and signs would result from fracture of the skull over the right Rolandic area?
3. State briefly the general considerations in the treatment of gunshot wounds.
4. (a) Name the different varieties of goiter. (b) When is removal of the thyroid gland indicated? (c) When is the ligation operation indicated? (d) When is no surgical interference indicated?
5. (a) Diagnose posterior dislocation of hip. (b) Describe briefly the necessary manipulations to reduce said dislocation. What is the after-treatment?
6. Describe the operation and name structures encountered in ligation of the superficial femoral artery at the apex of Scarpa's triangle.
7. (a) Describe the operation of removal of the appendix. (b) What are the indications for said operation?
8. (a) Describe the symptoms and signs of oblique fracture of head of humerus. (b) Describe briefly the treatment.
9. Describe briefly a typical case of acute empyema, giving all aids to diagnosis of said condition.
10. Give the diagnosis, course and prognosis of cancer of the rectum.
11. Describe the treatment of acute gonorrhea in the male.
12. Differentiate gallstones from right-sided kidney stones.

HYGIENE AND SANITATION

1. Indicate the limitations of private practice as compared with public health practice.
2. (a) What are the most important foreign ingredients in water? (b) Mention five methods of purifying water.
3. (a) What prevalent acquired defect in school children's eyes is directly due to school life? (b) Discuss the prophylaxis of eye defects.
4. Why should the registration of vital statistics be compulsory?
5. In what ways are health and efficiency of school children promoted by fre-

quent physical examinations? 6. Describe the modern method of dealing with an epidemic of diphtheria among school children. 7. What diseases are transmitted by animals and insects? 8. Discuss antityphoid inoculation. 9. Name ten preventable diseases and indicate the mode of prevention. 10. Discuss modes of dissemination of diseases which can be transmitted by indirect contact. 11. Discuss the efficiency of formaldehyde as a disinfectant. Describe most efficient method of using it. 12. Describe an efficient method of disinfecting excreta.

ANSWERS

GENERAL MEDICINE.

1. **TYPHOID FEVER.** The bacillus of Eberth is the pathogenic microorganism of the disease; it is conveyed by contaminated food or water, by flies and by fingers. *Symptoms:* Insidious onset, weakness, headache, epistaxis, vague pains. The temperature rises gradually, about 2° in the evening, and falling 1° in the morning. Diarrhea, tenderness in the right iliac fossa, enlarged spleen, and a characteristic rash which appears from seventh to twelfth day. During the second week the temperature remains at a uniform level; typhoid state and delirium may be present. The pulse becomes rapid, weak, and dicrotic; the heart sounds are feeble; the tongue is coated, fissured, and tremulous; sordes appear on the teeth; the abdomen is distended; the stools are yellowish and offensive (said to be like pea soup); the Widal reaction may be positive. In the fourth week the temperature becomes normal. *Pathology:* "Principally inflammation of the lymphoid tissue of the lower portion of the ileum, with more or less catarrh throughout the bowels. Peyer's Patches—first week.—Are swollen through infiltration of leucocytes, the surfaces raised and fawn-colored—the infiltration involves the submucous coat. The lesions are most numerous at the lower end of the ileum. Second week.—The surface becomes abraded; sloughs form, which are often bile-stained. Third week.—Sloughs come away, leaving ulcerating surfaces. Typical typhoid ulcers are thus formed. A few solitary glands undergo the same process. At the end of the week the ulcers begin to granulate, but healing is usually slow. Mesenteric glands may undergo the same changes, but more often become swollen, red, and tender only, or break down into cheesy masses. Other organs—Spleen and liver are enlarged; heart is soft and flabby. The voluntary muscles undergo granular degeneration; in fact, similar changes to those found after death from high temperature."

Diagnosis is made by the symptoms, mainly the Widal reaction (if positive), temperature, eruption, enlarged spleen, low leucocyte count, and diarrhea.

2. *Anasarca:* If the edema began at the feet and spread upward, the cause is probably cardiac disease. If it began in the face and spread downward, it is probably due to renal disease. It may also be due to trichinosis, in which case it will be found to have begun over the affected muscles. It is also found in Hodgkin's disease.

3. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at the end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

Calmette's ophthalmo-reaction: "One or two drops of 0.5 per cent. purified old tuberculin are instilled into one eye. Tuberculin ready prepared for this purpose is on the market. If tuberculosis exists anywhere in the body, a conjunctivitis is induced within twelve to twenty-four hours. This generally subsides within a few days. The method is not without some, though slight, risk of injury to the eye; and the test is absolutely contraindicated in the presence of any form of ocular disease. A second instillation should not be tried in the same eye."

Von Pirquet's method: "This is the most satisfactory of the tuberculin tests. Two small drops of old tuberculin are placed on the skin of the front of the forearm about two inches apart, and the skin is slightly scarified, first at a point midway between them, and then through each of the drops. In about ten minutes the excess of tuberculin is gently wiped

away with cotton. No bandage is necessary. A positive reaction is shown by the appearance in twenty-four to forty-eight hours of a papule with red areola, which contrasts markedly with the small red spot left by the control scarification."—(Todd's *Clinical Diagnosis*.)

4. In *cerebrospinal meningitis*, Kernig's sign is present, and examination of the cerebrospinal fluid (following lumbar puncture) will show the presence of the *Diplococcus intracellularis meningitidis*. In *acute anterior poliomyelitis*, both of these signs will be absent.

Treatment of acute anterior poliomyelitis: "During the acute stage the patient should be isolated and confined to bed. Mild laxatives and febrifuges may be used with some advantage. Hexamethylenamine (2 or 3 grains every two hours during the acute stage) has been recommended by Dana and others for the purpose of sterilizing the cerebrospinal fluid. Aspirin or morphine may be necessary for the relief of pain. Warm baths and lumbar puncture are also worthy of trial. The affected limbs should be wrapped in cotton wool. In the course of two or three weeks, if the acute features have entirely subsided, the use of massage and electricity should be begun. The treatment of the latter stages is chiefly surgical, and has for its object the prevention or correction of deformities."—(Stevens' *Practice of Medicine*.)

5. *Gastroenteritis:* Artificially fed babies in the hot, humid, summer months are especially prone to this infection, superinduced by the ingestion of unwholesome milk. Infants and children under two years are mainly attacked. In the *mild form*, the stools first attract attention; they are curdy, loose and foul. The fever is moderate and the child fretful. The character of the stools soon changes to a greenish yellow, and they become more numerous, five to six a day, and the fever rises to 102° to 103° F. If prompt measures are taken, recovery is rapid and quite certain. In the *severe form*, vomiting, with loose frequent spinach-green stools and high fever may be seen at the outset. Vomiting follows the ingestion of nearly all the food offered. The fever and inability to take food produce weakness and extremely rapid emaciation, and later a comatose condition with marked prostration. The fontanel is sunken and the pulse is weak. The stools may be streaked with blood and contain mucus. The fever frequently rises to 104° or 105° F., and death may be preceded by coma or convulsions. In the *toxic form*, the symptoms are severe from the outset. High fever and intense prostration are added to the vomiting and frequent stools (which are green and intensely foul). Cerebral symptoms soon supervene, and delirium and coma usher in the end.

Management: Place the patient in the coolest, cleanest, and largest room possible. A cotton slip and diapers only are to be worn. A competent nurse must be secured if possible. Reduce the fever by frequent cool sponging or tepid baths. An initial purge with castor oil or calomel is indicated. Stop milk in all forms for at least twenty-four hours, placing the child on a starvation diet of boiled water alone, or on barley water made with one ounce of flour to the quart. Resumption to cow's milk feedings must only be made when the stools resume the normal type.—(From Chapin and Pisek's *Diseases of Children*.)

6. *Headache*, due to *anemia*, may be felt in the forehead, vertex or orbit. That due to *hysteria*, is felt on the top of the head. That due to *neurasthenia*, is usually vertical, but may be felt as a band round the head. That due to *nasal disease* or *sinus disease* is felt at the root of the nose and running thence back to the occiput. *Ocular* headaches are frontal or occipital. That due to *constipation* or *digestive disorders* is frontal and orbital. That due to *uterine disease* is felt on the vertex or in the occipito-cervical region. That due to *cerebellar lesions* is felt in the cerebellar region. Migraine affects one lateral half of the head, particularly the eyeball. That due to *eyestrain* affects the frontal, temporal, and occipito-cervical regions.

7. *Epilepsy:* Epilepsy is a disease manifested or characterized by a periodic disorder of consciousness and by muscular convulsions, either of which may be absent in exceptional cases. According to the severity of the condition it is called *petit mal* or *grand mal*. The convulsions may be tonic or clonic, or may alternate. A family history of nervous disorders, alcoholism, or syphilis, poor physique, abnormal and difficult labors, rachitis, malnutrition, the infectious fevers, particularly scarlet fever, intestinal worms, injury to the

cranium, and disorders of menstruation are some of the causes of the disease. The pathology is unknown.

The attack is usually preceded by a peculiar sensation termed an *aura*, which may be sensory, motor, or psychic in character. The spasm generally begins at the free end of one extremity, and rapidly involves all the muscles of the body. The epileptic cry or groan is heard, and the patient falls unconscious. The spasm is first tonic in character, and gives way to a fine, general tremor, which is followed by a clonic condition; coma then ensues. There is at first pallor of the face, which is quickly followed by congestion and cyanosis; frothing at the mouth or nose, vomiting, and relaxation of the sphincter may occur. Various mental disturbances, automatism, mania, delirium, or persistent coma may follow one or more seizures.

Treatment: Surgical operations are of value in this disease only when there is evidence of injury to the brain and skull. The general treatment consists in the proper regulation of the diet, exercise, and sleep, and the administration of the bromides. Pastry of any kind, rich puddings, cake, pork, veal, ham, anything fried in grease, high seasoning, and alcoholic beverages are strictly prohibited. Tea may be given weak and in small quantities; coffee is allowed only for breakfast. The patient should eat slowly, masticate thoroughly, and should not overeat.

The bromides in their various combinations and preparations may be administered. To prevent the attacks, inhalation of amyl nitrite (m 1—5), or a few whiffs of chloroform may be tried. When the status exists, highly nutritious food must be given early, and perhaps by enema. Chloral may be judiciously administered. When other methods have failed, hypodermic injections of the bromides, strychnine, and whiskey may be tried.—(*Pocket Cyclopaedia*.)

8. The significance of this high blood pressure may be any of the following: Chronic interstitial nephritis, lead poisoning, gout, arteriosclerosis, angina pectoris, cardiac hypertrophy, and cerebral hemorrhage.

9. In *chlorosis*, the skin is generally yellowish-green, and the conjunctiva pale or yellowish. The pulse is soft, but of good volume, and a hemic murmur can generally be heard at the base of the heart. Palpitation of the heart and breathlessness are generally present. The blood is characteristic, and the diagnosis is made by an examination of this fluid. It shows (1) A great diminution in the amount of hemoglobin; (2) a slight diminution in the number of red corpuscles; (3) poikilocytosis; (4) occasionally a few nucleated red corpuscles; (5) a very slight leucocytosis.

Treatment consists in regulating the bowels, taking nourishing food, exercise, sunlight and fresh air. Iron in some form is specially indicated; Bland's pill is most frequently prescribed.

10. *Asthma* may occur as a symptom in cases of chronic nephritis (*renal asthma*), or in chronic heart disease (*cardiac asthma*); it may also be caused by the action of the pollen of certain grasses or plants on a particularly sensitive respiratory mucous membrane (*hay asthma*); certain irritants may also cause the condition (*bronchial asthma*.)

Treatment of hay asthma: Any existing nasal trouble must be found and removed or otherwise treated; a change of climate is often beneficial, a sea voyage or a sojourn in a mountainous district being of service; tonics, such as strychnine, quinine or arsenic, should be administered before and during the attack; the eyes may be washed with a solution of boric acid (about 1:50); the application of Dobell's solution in the form of a spray or of adrenalin solution (1:5000) on pledgets of cotton has also been recommended. Some have also advocated the treatment by antitoxic serum or pollantin.

11. The chief complication and sequelæ of scarlet fever are: Arthritis, or rheumatism, which may lead to suppuration or pyemia; endocarditis and pericarditis; otitis media, with suppuration; facial paralysis; bronchopneumonia; suppuration of the glands, particularly of the cervical glands; nephritis; uremia; anasarca.

12. Bronchopneumonia is most common in childhood and in old age; lobar pneumonia is most common in adults between 20 and 50 years of age.

Bronchopneumonia is a term applied to inflammation of the lungs which, beginning in the bronchi, finally involve the parenchyma of the lungs. This disease may occur at either extreme of life. Three varieties are described: (1) A simple, acute form, following a severe bronchial catarrh; (2) a secondary form, oc-

curring after the infectious fevers, tuberculosis, nephritis, cardiac disease, emphysema, and the lodgment of foreign particles in the bronchial tubes; (3) a rare suppurative form, with the formation of abscesses in the lung. In addition to the bronchitis there are scattered areas of consolidation and collapse throughout the lung.

Symptoms: In children the onset is marked by convulsions, high temperature (104° F.), violent cough, rapid respiration (60 a minute), intense dyspnea, rapid, feeble pulse, cyanosis, and cold extremities. Localized areas of dullness are present, but often not detected. Fine subcrepitant râles are heard posteriorly at the base of the lungs. Sibilant râles may also be present. The disease may be mistaken for lobar pneumonia, but the diagnosis can be made from the physical signs of each disease.

Treatment: Absolute rest in bed and a nutritious diet; the chest should be enveloped in a thick cotton jacket; the temperature of the room should be equable—about 65° or 70° F. If the bowels are inclined to be constipated, fractional doses (gr. 1/6) of calomel are advisable every hour until six or seven doses have been taken. In the earliest stages the tincture of aconite is of service. Its action should be cautiously watched, and as soon as the pulse becomes soft, the drug may be omitted. Usually six or seven doses are sufficient. If the temperature rises above 102.4° F., it should be reduced by means of a cold bath. Phenacetin may be given to control the temperature, but should not be used routinely. After the third or fourth day a flax-seed poultice containing mustard (3jss) may be applied to the chest and renewed every hour. After the poultice has remained on the chest about 2 hours, give the syrup of ipecacuanha (m 15) every 10 minutes until emesis is produced. Both these procedures should be repeated on the following day. When the poultice is removed, replace it by a cotton jacket. If the heart is weak, give cardiac stimulants.—(*Pocket Cyclopaedia*.)

OBSTETRICS AND GYNECOLOGY.

1. *Blue baby* is the name given to a newborn infant suffering from asphyxia livida. The condition is due to some interference with the feto-placental circulation, which results in an extreme venous congestion of all the fetal organs; this congestion is particularly marked in the right side of the heart, spinal cord, cerebral cortex, lungs, pleura, liver and spleen. There may also be present some disturbance of the respiratory center. The *treatment* consists in removing any foreign matter which may be present in the mouth or respiratory passages; in stimulating respiration by slapping the child's back or buttocks, or by sprinkling it alternately with hot and cold water, or by dipping it into hot and cold water; artificial respiration must be tried and persisted in so long as any sign of cardiac movement is apparent.

2. *OPHTHALMIA NEONATORUM*. **Causes:** The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. **Pathology:** The palpebral conjunctiva is first affected, then the ocular conjunctiva and cornea; the latter becomes hazy, ulcerates, may become perforated with escape of one or both humors and collapse of the eyeball. Adhesions of the iris, corneal opacities and staphyloma are other possibilities. **Prophylaxis:** Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. **Treatment:** Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

3. **Indications for the use of forceps** are: (1) *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother and child. (a) Impending exhaustion; (b) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3½ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (a) occipito-posterior, (b) mento-anterior face, (c) breech arrested in cavity. B. Evi-

dence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapsed funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both.—(Jewett).

Cesarean section (conservative). “*Indications:* The cases in which it is performed are: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the ‘positive’ indication for cesarean section; there is nothing else to be done. Flat pelvis having a conjugata vera of 2¼ inches or less, and justo-minor pelvis with a conjugata vera of 2½ inches or less, present this positive indication; (2) cases of more moderate pelvic contraction in which craniotomy is possible, but cesarean section is agreed upon to *save the life of the child*; (3) mechanical obstruction in the pelvis from fibroid, cancerous, bony, or other tumors which cannot be pushed up out of the way or be safely removed; (4) irreducible impaction of a *living* child in transverse presentations; (5) in women dying near the end of pregnancy the child, if alive, is rapidly delivered by *post-mortem* cesarean section; (6) various other obstructions from inflammatory adhesions, atresia, constrictions, etc., of the vagina, and uterine displacements, may rarely require the operation; (7) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (8) in placenta prævia, chiefly with a view to lessen the infant mortality attending the usual treatment of this complication.”—(King’s *Obstetrics*.)

4. In *tubal pregnancy* there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage.

5. *Mechanism of labor with a left mento-anterior position:* “The successive steps are: Extension—The head presents at the superior strait imperfectly extended, so that every case of face presentation may be said to begin as a brow presentation. There is also at first imperfect engagement of the presenting part, on account of the large diameters presented at the superior strait. Under the influence of the expulsive action of the uterus and the resistance of the pelvic walls, the brow, caught upon the pelvic brim, is held stationary, while the chin descends lower and lower by an extreme extension of the head. Molding, or an accommodation of the shape of the presenting part to the shape of pelvis, occurs to a moderate degree or not at all, because the face is a loose fit in the normal pelvis. The molding is confined to the back of the skull. Lateral inclination is a constant feature, so that one cheek is a little deeper in the pelvic canal than the other one. Descent of the presenting part follows the dilatation of the cervical canal, the descent of the chin being accomplished almost solely by the extension of the head, and not by a descent of the head as a whole. Anterior rotation of the chin occurs as soon as it encounters the resistance of the pelvic floor. Anterior rotation is followed by the engagement of the chin under the symphysis pubis. Then follows the delivery of the head by flexion and propulsion, the mouth, nose, eyes, and forehead sweeping over the perineum and appearing successively at the posterior commissure. Restitution and external rotation follow the escape of the head from the same causes that impose those movements upon the head in a vertex presentation. The delivery of the body takes place as in a vertex presentation.”—(Hirst’s *Obstetrics*.)

POLYHYDRAMNIOS.	TWIN PREGNANCY.
The uterine tumor is more definitely tense.	The uterine walls are not so uniformly distended and tense.
Fluctuation may be elicited.	Fluctuation is absent.
There is inability to palpate the fetal limbs.	A number of fetal limbs may be palpated.

POLYHYDRAMNIOS.	TWIN PREGNANCY.
The lower uterine segment is unusually distended, tense, and elastic; the presenting fetal part is recognized with difficulty.	There is no undue distention of the lower uterine segment; the presenting part of a fetus may be readily detected.
The fetal heart sounds are faint or altogether absent.	The fetal heart sounds are distinct; heart sounds of different rates, corresponding to the two fetuses, may be heard.

—(Dorland’s *Obstetrics*.)

7. The **LIGAMENTS OF THE UTERUS** are: (1) *Broad ligaments*, which extend outward on each side from the side of the uterus to the side of pelvis. (2) *Rectouterine ligaments*, which extend backward from the intraperitoneal portion of the cervix uteri to the peritoneal investment of the rectum. (3) *Round ligaments*, which extend from the uterus just below the Fallopian tubes, through the inguinal canal to the labia majora. (4) The *ovarian ligaments*, which extend from the superior part of the uterus, behind the Fallopian tubes, to the inner end of the ovary. (5) The *uterosacral ligaments*, which extend from the highest part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacroiliac synchondrosis.

8. *Cystocele* is a hernia of part of the bladder into the vagina, covered by the mucous membrane of the anterior vaginal wall. *Rectocele* is a hernia of the rectum into the vagina, covered by the mucous membrane of the posterior vaginal wall. The two conditions are generally found together. *Causes:* Lacerated perineum, prolapsed uterus, relaxation of the structures forming the pelvic floor, and subinvolution of the vagina after labor. *Symptoms:* A dragging sensation in the lower pelvic cavity; a feeling of distention at the vulva; loss of power in urination or **defecation**; tumor of anterior or posterior vaginal wall (or both) more apparent on straining; prolapse of uterus.

Hematocele is a collection of blood (generally) in the (pelvic) peritoneum or connective tissue. As a rule the hemorrhage is intraperitoneal and is the result of some accident in the course of an ectopic gestation.

Procidentia is complete prolapse of the uterus (or other organ.) As a rule the uterus first becomes retroverted, it then sinks till the cervix appears at the vaginal outlet, and then protrudes through the vagina and vulva and causes inversion of the vagina at the same time. It is generally due to laceration of the perineum, and follows rectocele and cystocele.

9. *Lacerated perineum:* “The parts are cleaned and a pledget of sterile cotton or gauze pushed up the vagina to stop any flow from the uterus obscuring the wound. The sutures (preferably of aseptic silk) are passed with a moderately curved needle about two inches long as follows: Beginning at the posterior end of the laceration (that nearer the anus), the needle enters the skin near the edge of the wound and follows a circular course until its point appears at the very bottom of the laceration (a finger of the other hand in the rectum guarding against its penetrating that canal); it then enters the opposite side of the laceration at the bottom of the wound and comes out of the skin opposite its point of entrance, and followed a similar circular course to that pursued on the other side where it first went in. The ends are loosely tied or secured by catch-forceps, until the requisite number of sutures are passed in a similar manner (half an inch apart), when the wound is again cleansed, the vaginal plug removed, and the sutures tied tightly enough to coapt the parts without injurious constriction, the order of succession in tying being that in which the sutures were passed.

In “complete” lacerations—those of the third degree—through the sphincter ani to the rectum, the operation is more difficult. The rectal tear is first stitched with *catgut* sutures (a short, curved needle being used) and going through the rectal wall only. The sutures are tied on the inside, so that the knots are on the mucous membrane of the bowel. They begin from above and come down to the sphincter ani, the cut ends of which are drawn out with a tenaculum while the sutures penetrate them. These *catgut* sutures need not be removed; they will digest in the

tissues and disappear of themselves. The posterior wall of the vagina is next sutured with fine silk, from above downward toward the hymen. Finally, skin sutures through the perineum itself, including muscles of the pelvic floor (as just described for lacerations of the first and second degree) complete the operation. The silk sutures may be removed in about a week. Antiseptic dressings are applied as after an ordinary labor, extra care being taken to keep the wound aseptically clean by daily irrigation with the creolin solution."—(King's *Obstetrics*.)

10. **PELVIC ABSCESS.** *Diagnosis:* "From the history of the case the source of the infection may usually be traced to a previous attack of gonorrhea, or a septic labor, or a criminal or ordinary abortion. The temperature and pulse run a characteristic septic course. Vaginal examination shows the uterus elevated towards the symphysis pubis and fixed, while posterior to the cervix, often obliterating the fornix and bulging the posterior vaginal wall, lies a hard, dense, at times fluctuating, shapeless mass, extremely tender on pressure. In the chronic stage a differential diagnosis from impacted fibroid is often possible only by operation. *Treatment* during the acute stages should be expectant as long as the patient's condition warrants it. Absolute rest in bed, prolonged hot vaginal douches, hot or cold applications to the abdomen, free catharsis, and morphine when indicated. When the abscess steadily increases in size and the symptoms show no improvement, operative interference is imperative. The simplest method is evacuation by direct incision into the abscess, posterior to the cervix, with subsequent drainage by gauze or rubber tubing."—(Child's *Epitome on Gynecology*.)

11. When the uterus does not return to (approximately) its normal size and condition within about six weeks after labor, the condition is called *subinvolution*. *Subinvolution* is caused by fibroid tumors, pelvic inflammatory conditions, early resumption of sexual intercourse, premature rising from bed, retained secundines, uterine displacements and adhesions, etc. It is characterized by enlarged uterus and irregular bleeding. In all cases rest in bed, copious hot vaginal douches, abstinence from sexual intercourse, correction of constipation, and the administration of tonics are beneficial. Any treatment should be preceded by thorough curettage. Displacements should be corrected.

12. An *erosion of the cervix* is an area on the vaginal surface of the cervix which is covered with columnar epithelium, and consequently presents a reddened, inflamed appearance. Some confusion has resulted from the application of the term *ulceration* to this condition. There is no ulcer and no granulating surface, for the whole area is still covered with epithelium. The erosion is caused by an irritant vaginal or uterine discharge (e.g. gonorrhea, endometritis). *Treatment:* A possible cause should be sought for and corrected. The general health will be improved by the administration of preparations containing iron, such as Bland's pill, Basham's mixture, and the four chlorides. Exercise, diet, and the condition of the bowels should receive attention. The local treatment consists in the administration of hot vaginal douches two or three times daily; the use of glycerine tampons for twelve hours, twice a week; the application of tincture of iodine to the cervix, once a week; and the application of silver nitrate, zinc chloride, pure carbolic acid, or Churchill's tincture of iodine directly to the cervical mucous membrane.

SURGERY.

1. *Bleeding from the stomach may be caused by:* Ulcer or cancer of the stomach; congestion of the portal circulation; cirrhosis of the liver; irritants; malignant fevers; acute yellow atrophy of the liver; acute gastritis; rupture of an aneurysm.

GASTRIC ULCER. *Etiology:* Injury, bacteria, hyperacidity of gastric juice, changes in the blood or blood-vessels of the stomach; it generally occurs in young people (20 to 30) and is apt to be associated with chlorosis. *Symptomatology:* Pain, localized in stomach, coming on soon after a meal, and of a sharp or cutting nature, and often relieved by vomiting; hematemesis; tenderness over the stomach; the condition is generally improved by starvation or by a milk diet; analysis of gastric contents shows an excess of free hydrochloric acid; there may be "occult" bleeding. Prognosis is guardedly favorable; hemorrhage and perforation are apt to be fatal complications; relapses are common; the mortality is about 10 per cent.

2. *Fracture of the skull over the right Rolandic area, might cause:* Paralysis of some of the muscles on the opposite side of the body, the muscles affected depending on the exact site of the fracture and consequent pressure; concussion; necrosis of bone or osteomyelitis; pyemia; septic infection; cerebral abscess; convulsions.

3. *Treatment of gunshot wounds:* "The treatment of wounds due to the leaden bullet is that of any other infected wound in which a foreign body is lodged. Hemorrhage, if present, should be checked at once, and if necessary the patient reacted from shock. For determining the position of the bullet, the x-ray is by far the best means. In the absence of the x-ray one should ascertain the direction from which the bullet was fired and the position of the body at the time, examine the clothing for the position of perforations in relation to the skin wound as well as to determine whether portions are absent, and see whether or not there is a wound of exit. After disinfection the wound may be explored for the bullet and any foreign body which has been carried in with it. This is best done with the sterilized finger, enlarging the wound if necessary. When deeply lodged out of reach of the finger, a probe may be employed. Various electrical devices have also been invented for the detection of bullets. The bullet may be removed with the finger, or with strong forceps, such as the sequester forceps or special forceps. The wound is then disinfected with bichloride of mercury solution and drained with gauze. When a large number of shot are scattered in the tissues, or when the exact location of a bullet is not known, less risk will often be taken in leaving the bullet than in a long or mutilating operation to remove it."—(Stewart's *Surgery*.)

4. *The different varieties of goiter are:* Parenchymatous, fibrous, cystic, adenomatous, and exophthalmic. As a rule every rapidly growing goiter should be removed; ligation of the superior thyroid arteries has proved successful in the case of goiters recognized early; ligation is also indicated in acute severe exophthalmic goiter; malignant growths should not be operated on unless recognized and treated early.

Parenchymatous goiter: "Operative treatment is indicated when there are symptoms referable to pressure on the air-passages, esophagus, or blood-vessels, especially if there are signs of commencing cardiac disturbance; and in goiters which are steadily increasing in size. The evidence of a goiter becoming malignant is also a reason for removing it by operation. Kocher considers it advisable to operate if the patient becomes breathless by making pressure on the goiter from side to side."

Adenomatous goiter: "The only treatment is to enucleate the adenomata or cysts from the gland. The thyroid is exposed by a transverse curved incision, the tissue covering the nodule is incised, and the adenoma shelled out."

Malignant goiter: "It is only in the earliest stages that a malignant goiter can be successfully removed. In the later stages complete extirpation is not to be attempted, as it usually involves the removal of a portion of the trachea or esophagus, and the operation generally proves fatal. Operative interference is often called for, however, for the relief of respiratory embarrassment. Tracheotomy may prove a very difficult and dangerous procedure, owing to the trachea being buried under the goiter and displaced or narrowed by it, so that it is not easy to reach the trachea or to introduce an efficient tube beyond the point of obstruction. A more certain method consists in exposing the goiter by an incision as for thyroidectomy, rapidly removing sufficient of the growth to expose the trachea and admit of a tube being introduced. If there is a retrosternal prolongation compressing the trachea within the thorax, a long flexible lead tube may have to be passed beyond the site of the compression before the dyspnea is relieved."

Exophthalmic goiter: "Excision of one lobe of the thyroid together with the isthmus and the pyramidal lobe is indicated in all cases that do not present degeneration of the heart muscle, with irregular pulse and low blood pressure. The superior thyroid artery of the opposite side may be ligated with advantage."—(Thomson and Miles' *Manual of Surgery*.)

5. *Backward dislocation of the hip* is of two kinds: (1) On the dorsum ilii; (2) on the sciatic notch. *Dorsal dislocation:* Head of femur lies on the dorsum ilii, and can be felt in the buttock. The obturator internus is ruptured in most cases. The short rotator muscles are lacerated. The trochanter lies well above

Nelaton's line and approximated to the anterior superior iliac spine. The leg is shortened two to three inches. The iliotibial band is relaxed. The leg is flexed, adducted, and inverted. The femur crosses the lower third of the opposite thigh. The toe rests on the opposite instep. A hollow exists in Scarpa's triangle. *Sciatic dislocation:* Similar to the above, except in the following:—The obturator internus tendon is intact and lies over the neck of the femur, holding it down in the sciatic notch. Shortening amounts only to one inch or less. The axis of the femur crosses the opposite knee. The great toe rests on the dorsum of the opposite great toe. *Treatment:* In posterior luxation of the hip joint the patient should be placed on a mattress on the floor, and then be anesthetized. The leg is then to be flexed on the thigh, and the thigh flexed on the abdomen; adduction is to be increased so that the knee is beyond the middle line of the body; then abduct, freely circumduct outward, and finally extend the limb so that it is parallel with the other.

6. In ligation of the superficial femoral artery at the apex of Scarpa's triangle, the patient should be recumbent with the thigh abducted, flexed and rotated outward, and the knee bent and resting on a sandbag. The surgeon stands at the outer side of the limb. An incision is made, about three inches long, in the line of the artery, with its center over the apex of Scarpa's triangle. This incision includes skin and superficial fascia; the internal saphenous vein is drawn aside or ligated; the fascia lata is divided; the inner border of the sartorius is drawn outward; the groove between the sartorius and adductor longus is opened; the internal cutaneous and long saphenous nerves are displaced; the femoral sheath is then incised, and the ligature passed from the side of the vein.

7. *Operation for Removal of the Appendix.*—"An incision is made at right angles to a line (at the junction of the outer and middle thirds) joining the umbilicus and anterior superior iliac spine, one-third being above and two-thirds below it. The cecum is found, and the anterior longitudinal band is traced down to the appendix which usually comes off from the inner side and runs inwards and downwards. If not found there, it should be looked for in the retrocecal pouch or on the outer side of the cecum. The mesoappendix should be ligatured and cut through, a collar of peritoneum turned back, and the mucous and muscular coat ligatured near the base and cut off. The peritoneum should be stitched over the stump, and then the stump should be invaginated into the wall of the cecum by running a purse-string stitch around it."—(*Aids to Surgery.*)

The indications for removal of the appendix vary according to the views of the surgeon. Some maintain that every case of appendicitis should be operated on as soon as the diagnosis is made. Others would operate only in case of rupture, or when suppuration occurs, or in cases which do not improve in a week or so, or in cases which are steadily getting worse. Probably all would agree in taking out every appendix that has undergone more than one mild attack.

8. "The symptoms in longitudinal and oblique fracture of the head of the humerus are broadening and flattening of the shoulder with projection of the acromion. The upper fragment passes upward and outward, and the lower fragment passes upward and inward to rest on the margin of the glenoid cavity below the coracoid process. The elbow is drawn from the side, there is some shortening, and the patient cannot abduct his arm. If the surgeon grasps the patient's elbow and holds it to the side and rotates the arm while with his other hand he grasps the upper fragment, crepitus is very positive. Examination develops wide separation of the fragments. The deformity cannot be entirely corrected, because the biceps tendon usually gets between the fragments, but a useful limb can usually be obtained. *Treatment:* Place the patient on his back upon a hard bed with a small, firm pillow under his head, abduct the arm above the head, rotate it outward so that the back of the hand rests on the bed, and hold it in place by sandbags. This position should be maintained for three weeks, at the end of which period the fracture can be treated for three weeks more as is a fracture of the anatomical neck. If the patient refuses to go to bed, treat the injury as a fracture of the anatomical neck, padding well over the tuberosities. The dressings should be worn for five weeks, passive motion being made after four weeks. In the above injury feel at once for the pulse, to see if the artery has been torn."—(*DaCosta's Surgery.*)

9. *Empyema* is generally secondary to pneumonia, tuberculosis, scarlet fever, or other exanthem, suppurative inflammations, or traumatism. The pneumococcus, streptococcus, and staphylococcus are the bacteria most frequently found. The condition is diagnosed by finding the symptoms of fluid in the pleural cavity; this is withdrawn by a needle and on examination is found to be pus; a leucocytosis is also present. The physical signs are those of fluid in the pleural cavity; that side does not move well, the percussion note is dull, there is absence of breath sounds, vocal fremitus and resonance are diminished. Left alone, an empyema may burst through an intercostal space, usually the fifth. The lung is collapsed in extent according to the amount of pus. The pleura, at first covered with lymph, soon becomes covered with layers of granulation tissue, the deeper part of which is converted into fibrocatrictial tissue, and the lung itself also undergoes some fibroid change. If the pus is let out early the lung and pleura soon expand, but if allowed to go on the infiltration of the lung and the density of the scar tissue covering it hinder expansion. Nature attempts to remedy this in various ways. (1) The other lung expands and pushes the heart over to the opposite side; (2) the chest wall falls in, the intercostal spaces are obliterated, and the spine is curved, with its concavity toward that side; (3) the abdominal viscera are pushed up; and (4) exuberant granulations form on the pleura. If a cavity still remains an operation is necessary. *Symptoms:* Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis.

10. "*Cancer of the rectum* is usually of the tubular or cylindrical-celled variety, and is occasionally the result of a malignant change in an adenoma. The disease may begin as an ulcer, or as a nodule beneath the mucous membrane which reaches a large size before ulcerating. In the former instance the growth usually extends annularly around the rectum, in the latter it increases in all directions. The consistency varies with the amount of fibrous tissue present; thus the mass may be soft, fungating, and friable, or extremely dense with an ulcerated surface, the margins of which are hard and everted. The softer varieties are the more malignant. Metastases may occur in the lumbar glands, liver, and peritoneum, but are comparatively rare and late. The disease is most common in middle life, but it may occur earlier and has been seen even in childhood. The symptoms may be slight or absent, until the disease is far advanced. There may be pain, a sense of fullness in the rectum, tenesmus, and the passage of pus, blood, or mucus. In the later stages the signs of stricture are evident and cachexia develops. Secondary fistulæ into the bladder, vagina, or opening externally may form. The diagnosis is made with the finger and the speculum. If the growth is high up, it may sometimes be detected by having the patient bear down while in the standing position. Death occurs in from one to five years, from exhaustion, obstruction, hemorrhage, or peritonitis."—(*Stewart's Surgery.*)

11. *Treatment of acute gonorrhea, in the male:* "Lessen the acidity of the urine by alkalies, give diuretics, and keep the bowels acting freely. Sedatives such as tincture hyoscyami are useful. All forms of alcohol should be forbidden, otherwise plenty of fluid taken. The patient should rest as much as possible. No local treatment need be adopted in this stage. When scalding ceases, copaiba or oil of sandal-wood, 10 minims three times a day or cubebs, may be given. Their action is diuretic mainly. Cubebs and copaiba may produce a bright-red, itchy, widespread rash. Injections should be used after all irritation has ceased. The patient should pass urine to wash out the discharge immediately before using the injection. A glass syringe is best, and the urethra should be distended by argyrol, 1 per cent. solution, or zinc sulphate, 2 grains to 1 ounce. The injections should be used every two hours at first, and not left off till five or six days after the discharge has ceased."—(*Aids to Surgery.*)

12. In *cholelithiasis*, the attack is sudden; the pain very severe, and generally localized in the right hypochondriac region and often spreading to right scapula and over the abdomen; vomiting, chill, fever, drenching sweats, feeble and rapid pulse are common; liver and gall bladder are swollen and tender; jaundice may supervene; the urine may show bile pigment and albumin; examination of the feces for a few days after the attack may reveal the calculus.

In *nephrolithiasis*, the pain is also sudden and very severe, begins in the lumbar region and follows the course of the ureter, and is often referred to the testicle and glans penis; nausea, vomiting, chills, fever, and sweat are common; strangury may be present; there is great prostration following the attack; there may be polyuria or suppression of urine; with the aid of a cystoscope or sound, the calculus may be found in the bladder; examination of the feces is negative.

HYGIENE AND SANITATION.

1. In *private practice* the physician has to wait for his patients, build up his practice, collect his fees or not (as the case may be), take his chance as to making a living, spend relatively large sums of money for equipment (including books, and postgraduate study), fight against competition and opposition of all kinds (both fair and unfair), and there is no provision for him in his old age except his own savings.

In *public health practice*, patients are provided for the physician, his salary is paid him, there is no fee collecting, a living is assured him, equipment and postgraduate study are also assured him, and there is a pension for him to fall back upon in his old age. In addition, he is compelled to keep up his studies, opportunities for research are provided, and he has a much wider view of life and the possibilities of his profession.

2. FOREIGN INGREDIENTS IN WATER. *Organic*: Particles of animal and vegetable matter; bacteria and other living organisms, animal and vegetable; gases; ammonia, nitrites, and nitrates. *Inorganic*: Particles of mineral origin; gases; salts (chlorides, sulphates, carbonates, silicates, nitrates, nitrites, phosphates), lead, iron, soda, magnesia, lime.

Contaminated water is purified by: Distillation, boiling, filtration, precipitation, and various chemical processes.

3. Myopia, hypermetropia, and astigmatism are the most frequent defects of vision in school children.

Precautions which should be taken in school rooms to protect the sight of scholars, should include the following: (1) The light should be ample, and should come from the left side or from behind the scholar, never from the front. (2) The windows should extend nearly to the ceiling, and should have proper shades. (3) Blackboards should be clean and black, neither glazed nor shiny, and must not be on the same side as the windows. (4) Schoolbooks should be of good paper with good clear type, and the lines amply leaded. (5) Pupils should assume correct attitudes in writing or reading. (6) Desks and seats should be of a proper size, style and arrangement. (7) Excessive study should be forbidden, and children should not be allowed to read when their eyes are tired. (8) Proper medical examination should be made of the eyes when necessary, and defects corrected as soon as possible.

4. The *registration of vital statistics* should be compulsory, because otherwise the figures would be incomplete and therefore of less (or no) value. The birth records are of value, to prove citizenship, and to prove age or descent. The death records are of value, in probate matters, in pension matters, to the physician and actuary. The records of infectious diseases are of value, to physicians, to school authorities, to health authorities, and as affecting quarantine. To the person making the return, there may be no value in it; to every one else the returns may be of the greatest value.

5. Frequent and efficient examination of school children is the only way in which to prevent the spread of infectious and contagious diseases, and to detect illnesses and physical defects in their incipient stages. As a result of a proper examination there will be prompt exclusion and isolation of any one suffering from a contagious disease, or coming from a house where such disease is; compulsory notification of all infectious and contagious diseases; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease or who have come from a house where such disease prevailed should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

6. There should be prompt isolation of sick and suspected until bacteriological examination has shown that the disease is not diphtheria. No one should be released from quarantine, even if not apparently sick, until cultures taken from the throat are shown to be negative. The tendency of the bacilli to persist in throat and nose for long periods of time after con-

valescence is established should not be forgotten. All children, and to a lesser degree adults, who have been in contact with the disease should have swabs made and cultures taken, and if positive results are obtained, must be isolated until negative results are obtained, preferably on two successive days. (From Gardner and Simonds' *Practical Sanitation*.) Injection of antitoxin, both curative and protective, should be undertaken; the schoolrooms should be sprayed with formalin solution and re-whitewashed.

7. *Diseases transmitted by animals*: Tuberculosis, rabies, glanders, anthrax, tape-worm, and other intestinal parasites, ringworm, diphtheria.

Diseases transmitted by insects: Typhoid, cholera, plague, tuberculosis, dysentery, anthrax, intestinal parasites, malaria, yellow fever, dengue, Texas fever, sleeping sickness, filariasis, relapsing fever, typhus.

8. *Antityphoid inoculation*: "No hygienic measure discovered in modern times compares in value with the beneficial effects which result from the prophylactic inoculations of soldiers against typhoid fever. During the Spanish-American war, out of a total strength of 107,793 men, there were 20,738 cases of typhoid fever and 1,580 deaths, representing 86.24 per cent. of the entire mortality of the war. During the first eighteen months after antityphoid vaccination had been introduced into the United States army, 12,644 persons were vaccinated. Five cases of typhoid occurred among these men, but no deaths, or 0.39 cases per thousand vaccinated persons. During the same period in the remaining six-sevenths of the force there were 418 cases and 32 deaths." (Bergey's *Hygiene*.)

9. *Ten preventable diseases with mode of prevention*: Malaria and yellow fever, by extermination of mosquitos; smallpox, by vaccination and revaccination; plague, by destruction of rats; Malta fever, by avoiding the milk of goats; hydrophobia, by the systematic and long-continued muzzling of all dogs; dengue, by the extermination of mosquitos; typhus, by the extermination of lice and bedbugs; ophthalmia neonatorum, by the use of silver nitrate solution in the eyes of all newly born children; foot and mouth disease, by use of boiled milk.

10. *Dissemination of diseases by indirect contact*: "Diseases like smallpox, measles, and scarlet fever are transmissible by direct contact; and diseases like typhoid fever are usually transmissible by indirect contact. Some of the diseases, however, which are frequently disseminated by direct contact may be, and often are, disseminated indirectly through the medium of food infected with the specific microorganisms, or through the agency of flies or other insects whose bodies have become infected by coming in contact with infective materials. A number of diseases, prominent among which are those due to animal parasites, are disseminated through the use of meat derived from infected animals, through water polluted with animal excrement, or through green vegetables which have come in contact with such excrement. In addition to these there are some diseases in which the infective agent passes one of its cycles in the body of an insect, and is disseminated through the bite of such infected insect. The disease which is best known as being disseminated in this manner is malaria, which is disseminated through the bite of infected anopheles, while filariasis is believed to be disseminated through the bite of another mosquito, a species of culex, and yellow fever by the bite of still another, the stegomyia fasciata."—(Bergey's *Hygiene*.)

11. Formaldehyde is an effective disinfectant if properly applied; it has the advantage of not destroying fabrics; but it is not poisonous to the higher forms of animal life and does not kill vermin such as rats, mice, bedbugs and roaches. It is capable of disinfecting rooms, clothing, and fabrics; but it is inadequate for bedding and upholstered furniture.

12. Chloride of lime is well adapted for the disinfection of excreta. Eight ounces of chloride of lime should be dissolved in a gallon of water, and some of this solution should be placed in the vessel which is to receive the discharge. One or two quarts are then added, and after thorough mixing of the stool and the disinfectant, the two are allowed to stand for one hour.

Myopathia Rachitica.—E. Baumann reports the case of a young child who was seized with an acute attack of fever, pain in the arms, and paralysis. These were diminished in response to the galvanic and faradic currents, but no reaction of degeneration. Antirachitic diet effected a speedy cure.—*Korr. Bl. f. Schweiz. Ärzte*.

INTESTINAL STASIS FROM THE STAND- POINT OF THE INTERNIST.*

BY E. L. EGGLESTON, M.D.

BATTLE CREEK, MICH.

BATTLE CREEK SANITARIUM.

I HAVE no apologies to offer for bringing before you a paper on the subject of "Intestinal Stasis from the Standpoint of the Internist." For, in my opinion, there is no subject before the medical profession today that is receiving more respectful attention and none the proper solution of which will bring to us more respect from the large class of chronic invalids that is looking for relief. Moreover, I feel very confident that the great majority of such cases belong to the internist, particularly so in all but the later stages of their trouble. That the profession is interested in this subject is proven by the fact that probably in every issue of our prominent medical publications today, some phase of this subject is under discussion.

Lane of London, during the past few years, has been one of the foremost in calling attention to the disastrous effects of intestinal stasis, especially stasis in the small intestine, and in advocating advanced measures for the relief of the same. And his opinions, while considered by many to be radical, have done more to call respectful attention to this condition than those of any other one observer.

Stasis at some point in the intestinal tract, especially the colon, allows for the rapid development of the anaerobic bacteria normally found here, with the result that the protein material present is broken down into simpler products, some of which, such as indol, skatol, paracresol, and others, are of a toxic nature, and, when absorbed into the blood, may cause a serious disturbance of the functions of the vital organs, the nervous system being especially sensitive to their action. It would seem that the majority of individuals consulting physicians are subject in a greater or lesser degree to some disturbance of this kind. Especially is this true of the large class of individuals suffering from chronic illnesses. In all probability there is a definite relation between intestinal stasis and the appearance of the symptoms exhibited by these individuals.

Some observers are of the opinion that intestinal stasis results usually from some mechanical obstruction, and hence we hear a great deal about Lane's kinks, Jackson's membranes, the bands of Reid, etc., conditions which they believe may have been congenital, and the one way to relieve the individual is by resorting to surgical measures. But from the standpoint of the internist, it would seem

rather that in the beginning of these cases the trouble was of a functional character entirely, not originating in infancy, and as a result of stasis for abnormal periods of time in some portion of the intestinal tract, a mild inflammatory condition is set up at this point, resulting in adhesions of greater or lesser severity which may require surgical interference. These are terminal conditions which are rarely exhibited in the early stages of intestinal stasis.

In my opinion, the habits of the present day generation have a great deal to do with this condition. There is an unfortunate lack of education as to the care of the gastrointestinal tract. The individual has no conception of the necessity for providing proper foods, hence he selects his diet purely from the standpoint of gratifying his palate, and the result has been a concentrated diet providing insufficient bulk. The diet has also been unsatisfactorily balanced in that it contains an excess of protein material which is very prone to undergo putrefaction. The high tension under which so many people work causes them to be careless of the calls of nature. The mechanism controlling intestinal peristalsis, particularly that part having to do with the act of defecation, is a rather delicate one. It is quite probable that under normal conditions, the presence of solid material in the rectum excites general peristalsis which results in emptying the greater part of the colon. Unfortunately, where the desire is repeatedly ignored, as is apt to be the case with those engaged in sedentary occupations, the function of this mechanism seems to be lost. It is then quite possible that feces remain in the rectum and sigmoid for abnormal periods of time (Fig. 11), and as the result of this retention a mild inflammation of the parts is set up, with a spastic contraction resulting (Figs. 2, 13, 18.) In these cases, an examination of the sigmoid and rectum by means of the sigmoidoscope reveals the presence of a quantity of foul smelling feces which the patient is unable to expel. The mucous membrane is markedly congested and no doubt the inflammatory process extends to the outer walls of the bowel, allowing for adhesions which bind down the pelvic colon, thus forming a mechanical obstruction. By some it is considered that this chronic stasis is an etiological factor in the production of cancer. With the spastic condition which results from the local colitis, we have an abnormal retention of the intestinal contents in other parts of the bowel, particularly in the cecum (Figs. 2, 6, 8), and later on, probably as the result of ileocecal valve incompetency (Figs. 2, 6, 13, 18), in the terminal ileum. With this retention and the presence of putrefactive bacteria, we have the production in excessive quantities of those products of protein decomposition that we have every reason to believe are toxic in character.

In the early history of cases of an atonic character (Fig. 7), no very great discomfort results from

*Read before the Forty-Second Annual Meeting of the Northern Tri-State Medical Association, Ann Arbor, Mich., July 13, 1915.

the constipation. Some individuals will tell you that it has been their habit to have an evacuation only once every other day, or once every second or third day, but there comes a time a little later on when the individual is conscious that he is not in good condition. He suffers from frequent headaches, his tongue becomes coated, his breath is foul, he is depressed mentally, and he seeks some artificial relief. Usually he resorts to cathartics, and the immediate results are so satisfactory that he concludes it advisable to resort regularly to some measure of this character. Because most drugs used as cathartics are injurious to the mucous membrane of the intestinal tract, and inasmuch as their use is something like whipping a tired horse, it is only a question of time when the individual reaches the limit of such treatment, and this ordinarily leaves him in a state of chronic invalidism. The colon has been so injured because of the chronic irritation and the mild inflammatory conditions which have been set up, that it is found under careful examination made with the Roentgen ray to be bound down by adhesions at certain points and to be in such a condition that normal function is out of the question. And this is a probable explanation of a large proportion of the cases of patients who, suffering from general ill health without definite organic disease, seek relief at the hands of the physician. The diagnosis usually made is biliousness, neurasthenia, psychasthenia, liver trouble, neuritis, rheumatism, etc. Practically all exhibit a functional nervous disturbance, as headaches, insomnia, mental depression, forgetfulness, irritability, subnormal temperature, neuralgias, rheumatic aches and pains, cold perspiring hands and feet, mental hebetude, etc., and so it is quite natural that they should be diagnosed as neurasthenics, a term which means just about as much as the term "rheumatism."

Are we confident that because there is an intestinal stasis there results an absorption of toxins of intestinal origin? The proof of this, it seems to me, hardly needs demonstration. The results of our therapy would apparently prove this. Why is it that a person exhibiting symptoms such as have been mentioned above is relieved by a thorough purge? Why is it that the individual himself appreciates very decidedly the relation which exists between the disturbed intestinal function and his distressing symptoms? It is true that some are able to withstand the ill effects of intestinal stasis for a long period of time, not because there is not a decided increase in the toxins but because of the body's ability to protect itself from them. We are endowed with a triple line of defence against these toxins, the first line of defence being the intestinal mucosa which protects by its secretions that have a restraining effect on the intestinal bacteria. The bacterial toxins are in some way rendered harmless by them for an equal amount of toxin administered by mouth and by way of the portal vein. In the first instance the toxic symptoms were much less than when injected into the portal vein. It is quite well demonstrated clinically, as in obstruction of the intestinal tract, that when the intestinal wall is in part denuded of its mucosa, the toxemia is very much more apparent.

The second line of defense is the liver. Here it is that the indol, skatol, and phenols are conjugated with the sulphuric and glycuronic acids to form products that are very slightly toxic compared with their antecedents. No doubt the liver has to bear the brunt of the attack and it is only because of its ability to form less harmful products of those intes-

tinal toxins that the body is so immune from harm. It has been demonstrated that it retains a part of the phenol and indol which is not conjugated. Schupper is authority for the statement that the liver exerts, owing to the biochemical activity of its cells, a marked toxicolytic action on toxins and alkaloids. He demonstrated that the toxicity of the alkaloids—atropine, pilocarpine, cocaine, and apomorphine, was reduced 50 to 75 per cent. Combe has worked out a urotoxic coefficient which was demonstrated by experiments on animals, both before and after ligation of the portal vein, and the conclusion is that the toxicity of the urine is proportional to the degree of hepatic insufficiency.

The third line of defence is the glands of internal secretion, the thyroid, the suprarenal, and the pituitary body. From our more recent knowledge, we are certain they do exert some antitoxic action, as evidenced in the absence of their function in diseased conditions.

It seems, then, that the body is well fortified against harm from the action of toxins of intestinal origin; and probably symptoms of intestinal intoxication result as frequently from the body's losing its power to cope with what might be considered a normal amount of these materials as from an excessive formation of them.

In another class of cases, the intestinal stasis seems to result from a disturbance between the vagus and the sympathetic nervous systems. Under the term "vagotonia," as described by von Noorden and his pupils, we have a condition where, as the result of a lack of balance between the vagus and sympathetic systems, we have a spastic contraction of certain portions of the intestinal tract, especially the left half of the colon, that is not secondary to colitis. Frequently, we observe cases where constipation begins with a definite nervous disturbance from excitement of different kinds. But coincident with the spastic contraction of the bowel, we have a very definite retention evidenced by extreme sensitiveness over the entire course of the colon, especially over the sigmoid and around the terminal ileum (Figs. 5, 17, 18), cecum, and appendix regions. This seems to result in a vicious circle—the spasticity caused by the disturbed nervous condition resulting in intestinal stasis, and intestinal stasis resulting in the increased production of intestinal toxins, the absorption of those toxins having a deleterious effect on the nervous system which is already in a disturbed state. These probably are the most difficult cases to manage that the physician encounters, and unfortunately, they seem to be decidedly on the increase. Frequently, in such conditions, a diagnosis of chronic appendicitis is made and the appendix removed, but inasmuch as the colon as a whole is in a disturbed state, little if any benefit is derived. Frequently, the trouble is only aggravated by the operation.

No matter whether the symptoms of intestinal toxemia result from the slower processes first described, or whether they have developed rapidly as the result of the second condition, they ultimately come to resemble each other very decidedly. We have the loss of weight, the chronic headache, the disturbed appetite, the furred tongue, the depressed mental condition, and the subject suffers from phobias of different kinds. In many instances the skin exhibits a bronzing, leading to the diagnosis of probable Addison's disease. In other cases, we have tachycardia, and the case resembles one of hyperthyroidism. In the majority of cases we have a low blood pressure, although by many observers

the toxins of intestinal origin are considered to be a decided factor in the production of cardiovascular-renal disturbance, where we have an exceptionally high blood pressure.

With stasis of a marked degree in the cecum, we may have a failure of competency of the ileocecal valve which allows for the stasis extending to the terminal ileum. With the lower coils of the ileum loaded with fecal material, we may have this portion dragged down from its normal position into the pelvis, producing decided tension on the mesentery and probably greatly exaggerating certain of the nervous symptoms so common in these conditions. With this malposition and mild inflammatory processes at certain points, we probably have a thickening of the mesentery at the point of greatest tension which may result in a Lane's kink (Fig. 3), which further aggravates the ileal stasis. With the introduction of the anaerobic bacteria of the colon into the ileum, the toxins are produced at a place where absorption is very active and where the mucous membrane has not been trained to reject them, the result being that the body is compelled to cope with an excessive amount of the intestinal toxins.

In cases of spastic constipation where the iliac and pelvic colon is the location of the spasticity, Case has called attention to antiperistalsis which he has observed in a number of cases and this no doubt is a decided factor in producing the marked dilatation of the cecum and in breaking down the competency of the ileocecal valve in certain forms of colitis. Alvarez, in a paper read before the Section of Physiology and Pathology of the American Medical Association at its last meeting in San Francisco, describes a form of antiperistalsis, and his theory is that the peristaltic waves move from the more irritable regions downward toward more quiet segments; but with an irritation at some point low down in the tract, impulses may arise that move upward, which check the progress of the intestinal contents and may even reverse the current. These are very interesting observations and should indicate to us the necessity for relieving the local inflammatory areas which are apt to be localized in the sigmoid or even in the ampulla or rectum.

With this picture of intestinal stasis before us, and the resulting toxemia, and the disastrous effects of the toxemia upon the functional conditions of the organs of the body, what can be done in the way of relief? In deciding upon our therapy for this condition we must keep in mind certain definite conditions. It would seem that the first important thing to consider would be to provide a diet which will stimulate peristalsis, lessen putrefaction, and at the same time afford sufficient nutrition to provide for more energy and to replenish the organs and tissues of the body that are already decidedly below par in their nutrition. We are beginning to appreciate the necessity for a more bulky diet, and early in the history of many of these cases of intestinal stasis careful attention to the frequent relief of the bowel of the fecal contents, an appreciation of the harm which results from inattention to the natural desire in this respect, and a proper regulation of diet are sufficient to relieve the condition entirely. But we may make the mistake of trying to increase the bulk of the diet at the expense of its nutritive value. Unless the nutrition of the body as a whole can be improved, these cases rarely respond satisfactorily, no matter what the character of the treatment may be. To lessen

putrefaction we must reduce the proteins to the minimum. In order to accomplish that, it will be necessary practically to eliminate flesh foods from the dietary, and certain of the legumes must be prescribed in moderation. In cases of vagotonia, where there is an intense spasticity, particularly of the descending colon with an irritation of the remainder of the colon, we find too bulky a diet not well tolerated and it frequently aggravates the unfortunate condition.

In cases where we have an atonic condition we are able to resort to physical measures with very great advantage. Massage, manual and mechanical movements, exercises which develop the abdominal muscles, supports which increase the intraabdominal tension—all are of great value. The above mentioned, in spastic conditions of the bowel, must be used very guardedly and probably more advantage will be obtained from rest, sedatives, and the careful and judicious use of hydrotherapy which improves the general nervous condition of the body and tends to equalize the circulation, preventing congestion of the blood, which is so apt to occur in the visceral region. By means of hydrotherapy we are able also to stimulate very decidedly the antitoxic secretory and excretory organs upon which we are depending for our protection against the toxins of intestinal origin.

We frequently are able to change the culture media of the intestinal tract and thus lessen putrefaction. The free use of lactic-acid-forming ferments does much to check the growth of the anaerobic putrefactive bacteria and tends to encourage the growth of the fermentative bacteria which, so far as we know, have no injurious effect. The introduction into the bowel of certain strains of the lactic-acid bacillus is very beneficial in many cases. We frequently find it necessary to resort to laxatives of some character, and this demands very careful consideration. Unfortunately, the limits of this paper are too narrow to discuss this point satisfactorily. In brief it may be said that there are very few laxatives that are not harmful to the intestinal mucosa. It is probable that we are able to resort to the use of the mineral oil and bulky substances, such as agar-agar and bran, in the majority of cases without injury and with great advantage. At times it would seem that antiseptics are of some value, although the majority of observers fail to give a very high place to materials with which it is attempted to produce intestinal asepsis.

Where we have a decided colitis we frequently find it very essential to resort to bowel irrigations. In some cases it seems impossible to accomplish any desired results without relieving the irritation of the colon. By means of irrigation with physiological saline solution, mild alkaline solutions, and especially with oil, we remove the offensive material, soothe the mucous membrane, and provide lubrication which tends to relieve very materially the intestinal stasis. Some observers are advising irrigation by means of appendicostomy or cecostomy, claiming that very much more can be accomplished by these mild operations than by the more mutilating operation of short-circuiting or the removal of portions of the colon.

In cases where the intestinal stasis results from ptosis of a congenital character, the physician is confronted with a condition which will most surely tax his ingenuity. Surgery offers no relief, and the internist may receive great help from the orthopedist. If physical therapeutics can be re-

sorted to early in life, much can be done to train the abdominal organs into more perfect functional condition. If the individual reaches adult life, it seems almost impossible to improve the situation and the patient early falls a prey to some acute infection, and having little resistance, his existence is usually cut short before he reaches middle life.

When is it proper to advise surgery for the relief of intestinal stasis? From the observation of a large number of cases that have been surgically treated, I am of the opinion that it is rarely advisable to resort to surgical intervention except where we have definite organic obstruction. The malposition of the intestinal tract may have no bearing whatever on its function. As the result of a large number of *x*-ray studies it would seem that position is of very little importance. Previously, great stress has been laid upon vicerptosis, prolapsed colon, etc., but in my opinion a prolapsed colon without definite organic obstruction is of very little importance. For the relief of the adhesions which are sometimes found, surgery may be valuable, but unfortunately, a greater number of cases exhibiting marked disturbance as the result of adhesions are post-operative cases, and I doubt whether it is advisable to manipulate the intestines as it apparently seems necessary to do in the endeavor to relieve intestinal stasis, for such manipulation will probably leave a condition where there will be more adhesions than there were previously.

Dr. John G. Clark of Philadelphia, in a paper read recently before the Allegheny County Medical Society, has this to say with reference to the necessity for surgical interference: "Discussing this question as a surgeon, I almost stand in the position of holding a brief for the physician, for my surgical experience has confirmed my original statement so frequently reiterated, that the cases of intestinal stasis primarily belong to the medical man. The frequency of cures at his hands are much more easily enumerated than are the scores of failures, and I do not concede this field of endeavor to him because of the brilliancy of his therapeutic endeavors, but from the observation that it is only the occasional case which the surgeon will handle with greater success. Each division of medicine has made advances, but neither is in a position to boast of any very great progressive movement."

Bainbridge, a very ardent follower of Lane, is authority for the statement that in his opinion, with proper medical attention, not more than one out of ten, or possibly one out of twenty, of these cases should be compelled to seek surgical relief.

It would seem that there should be no antagonism between the internist and the surgeon with reference to these cases. Certainly, in their early stages they belong to the internist. In cases where we have to contend with malignant growths (Figs. 9, 10, 12, 14), tumors pressing on the intestinal tract from without, tuberculous lesions, strictures, following injury, or ulcers, there is no question but that surgery is the one means of relief. But I am of the opinion that the short-circuiting operations, or the removal of the colon or portions of the colon, in the absence of definite organic obstruction, are to be condemned for the results are not such as to be encouraging, and in the majority of cases the patient is left in a far more unfortunate condition than he was previously.

In conclusion, I wish to acknowledge my obligation to Dr. J. T. Case, who has made the *x*-ray studies of my cases and who has kindly furnished

the illustrations and slides; and further, permit me to say that, in my opinion, every case of intestinal stasis is deserving of *x*-ray study, the results of which will be of inestimable value to the internist in directing the course of his therapeutic effort and in deciding when the case is one that should be referred to the surgeon.

EXPLANATION OF PLATE.

FIG. 1.—(14,455) Normal colon.

FIG. 2.—(10,870) Marked spasticity in the left half of the colon. Right half of the colon considerably dilated, the dilatation occurring longitudinally as well as in the caliber of the bowel. Hepatic flexure higher than the splenic. Ileocecal valve incompetent as is the rule in these cases. Colon enema-filled.

FIG. 3.—Illustrates a marked degree of ileal stasis, also a moderate colonic stasis. Proximal to the cecum there is a characteristic Lane's kink.

FIG. 4.—(22,110) Shows the enema-filled colon in a case of multiple diverticula where the diverticula are few and scattered and are probably of no consequence.

FIG. 5.—(13,357) Roentgenogram 26 hours p.c., showing the colon filled throughout. The distribution of the barium boluses in the left half of the transverse and in the descending and iliac colon being characteristic of spasticity.

FIG. 6.—(9661) Enema-filled colon in a case of marked dilatation of the cecum and ascending colon, with spasticity in the left half. The ileocecal valve is incompetent, permitting a number of feet of the ileum to fill by the enema.

FIG. 7.—(42,849) An atonic colon, the caliber being much dilated throughout. I have always felt that this patient really had pellagra, but as far as I am aware, such a diagnosis was never confirmed. Such a colon is characteristically seen in cases of pellagra.

FIG. 8.—(11,076) A trace in the pyloric end of the stomach and in the duodenum; a large collection of barium in the upper part of the jejunum and the colon filled from cecum to middle of the descending. Below the middle of the descending colon is a streak of mucus which has imprisoned a certain amount of barium, enough to make it show.

FIG. 9.—(7439) Cancer of the colon. The arrows point to the stenosed bowel on the proximal side of which the barium is banked up in the dilated bowel. This roentgenogram was made about three days after the meal.

FIG. 10.—(16,188) Case of acute small intestine obstruction. For illustration purposes, the barium-filled bowel is preferable to the air-filled bowel.

FIG. 11.—(44,588) A typical case of rectal stasis. The head of the barium column reached the rectum toward the end of the first day, and at the fiftieth hour the barium meal residue is banked up below the splenic flexure, the majority of it occupying the rectal ampulla.

FIG. 12.—(7717) Chronic small bowel obstruction, this being indicated by the gas-filled small bowel. The colon is partially filled by enema and the stomach is shown gas-filled. The rubber tubing is introduced through an appendicostomy opening.

FIG. 13.—(42,833) Shows the same case as in Fig. 16 a few minutes later after the bowel had been filled by enema. Note that the ileocecal valve is incompetent and that the iliac colon is unusually spastic. Stereoscopically it is quite evident that the rounded shadows which I interpret as diverticula are extraluminal. Of course, there is no doubt about their being diverticula.

FIG. 14.—(11,332) Arrow 1 points to the barium which was injected through a tuberculous sinus, whose external opening was in the lumbar region, posteriorly. Arrows 2 point to barium in the bowel 100 hrs. p.c. Arrow 3 points to the top-most point to which the enema column reached. A gap between arrows 2 and 3 corresponds to the area of obstruction.

FIG. 15.—(42,240) Diverticula of the colon seventy-two hours after the meal. They are largest and most numerous in the iliac colon.

FIG. 16.—(42,793) Large multiple diverticula. This roentgenogram was made seventy-four hours after the meal.

FIG. 17.—(13,566) Spastic, enema-filled colon. In this case the spasticity is shown not so much in the narrowing of the iliac and pelvic colon, as in the early response to irritation, evident by the peristaltic wave which began in the cecum and had reached the hepatic flexure by the time this plate was made.

FIG. 18.—(45,008) A typical case of spasticity of the bowel with ileocecal valve incompetency and stasis in the appendix. This roentgenogram was made at the twenty-sixth hour. The left half of the bowel is spastic. The right half of the bowel is widely distended. The appendix is shown filled with barium. The white arrows point to the terminal ileum which still contains barium.

FIG. 19.—(14,368) The track left after a recent mass peristaltic movement. This is due to the trace of bismuth left in the track of the onward rushing mass and is not due to spasticity of the bowel.

Treatment of Facial Erysipelas.—Nobécourt claims to have obtained excellent results in the treatment of this condition by the continued application of a 5 per cent. solution of methylene blue. The solution is applied by a camel's-hair brush or a cotton swab to the diseased surface and for an inch beyond on the surrounding healthy tissue. The dressings and applications are renewed twice daily, usually morning and night, and as often as it seems necessary in order to hasten recovery. —*Journal de Médecine.*

SOME THERAPEUTIC SUGGESTIONS DERIVED FROM THE NEWER PSYCHOLOGICAL STUDIES UPON THE NATURE OF ESSENTIAL EPILEPSY.*

By L. PIERCE CLARK, M.D.,

NEW YORK.

FROM a neurological point of view, I am not one of those optimists who believe that the strict fields of neurology and psychiatry are coming closer together in either the study or treatment of nervous disorders. I believe that the view that they are, is misleading as well as false. During the past decade especially a distinctly new tendency has been born in the field of psychiatric research, or better, a revival has come about, the movement being a more complete and accurate unfoldment of the older school of psychiatrists who saw that the problem of psychotic individuals was based upon inadequacies, conflicts, and unsatisfied longings as the essential motive forces in inducing various types of mental reactions. This older view was for the most part set aside or greatly obscured by the somatists who saw, as they thought, an opportunity to introduce the histopathological researches in psychopathology as a direct interpretation of abnormal mentation. It was but a renewed attempt to bridge the gap between the soma and the psyche, and to work out a psychophysical parallelism between cortical cell changes and psychotic processes. They strove to prove or implied that these two processes had a relationship of cause and effect. If one will carefully review the psychiatric literature of fifty years ago and compare it with that which is now current, aside from the product from the numerically small new school, the observer is at once struck with the much more simple, natural and harmonious light in which case material was formerly considered. To-day one often obtains accounts of the psychoneuroses and psychoses in which the psychologic settings are obscurely hidden in a lengthy report of nephritic or gastrointestinal exposé. When one at last arrives at the momentous scene of vital conflict, where the psychosis really develops, he finds the situation buried beneath a lugubrious account of psychiatric cant-phrases that are often meaningless. The patient's precise behavior, conduct and disordered train of thought are omitted. Formal descriptions of the psychoneurosis and psychosis are well enough, but the key to their interpretation and application involved in them should be at hand. The simple, natural, unvarnished tale of how the toils and conflicts of the patient's real difficulties came about is omitted. I submit, if we are to be of any therapeutic service in such a problem we must know how the particular settings of the psychosis erupted from the plane of everyday happenings and what sort of makeup our patient really possesses. No doubt the neurologists have been the greatest offenders in this respect. They have attempted to force the psychotic states into direct structural brain interpretations. Often one hears it said that the simple accounts of daily happenings, thoughts and conduct of a psychotic individual are not scientific observations and one must pass them over hastily to reach the laboratory analyses and the strictly structural reflex and anatomic study of the case. This prolonged and somewhat fixed attitude on the part of the neurologist has already driven many workers on the func-

tional disorders out of the neurological field and they are taking their studies and investigations elsewhere for report and discussion. The great body of general practitioners and the laity are seeking a therapeutic release from the old formal structural approach to the psychoses and neuroses. Special sanatoria are multiplying at an enormous rate to handle these disorders and the average neurologist is left with his palsied and brain tumor invalids to patch them up as best he may.

It is not sufficient for us to recognize that structural or organic neurology is inadequate to handle the nature and treatment of the neuroses but that even many organic disorders are incompletely understood until one gains a proper evaluation of the psychologic settings involved. The so-called organic dementias and cerebral palsies have individual problems which can be approached only on psychologic grounds. For instance, no one pretends to say that the degree and depth of lesion in paresis has any essential parallelism to the degree of psychic dilapidation that ensues. If it proves true that there is no essential parallelism between this apparently organic paradigm disease of the brain and its attendant psychosis, one must of necessity consider the latter on psychologic grounds in the terms of its psychogenesis. In no field is the above tentative statement more true than in so-called genuine or essential epilepsy. This nervous disorder has been commonly accepted as definitely organic in nature and origin, although not a few epileptic brains have been found entirely normal histologically, and at least in one instance the brain of a profoundly deteriorated epileptic was used for the study and demonstration of a so-called normal brain (MacCurdy.) In view of the foregoing not a few of us have turned our attention entirely away from attempts to consider essential epilepsy in terms of histologic interpretations and have approached the whole problem from the psychobiologic side. We believe that the epileptic reaction or attack in this convulsive disorder has an individual psychology quite unique.

Before entering upon the specific therapeutics of our thesis I may briefly sketch the essential results of the newer studies. First, that there is a definite makeup or inherent defect of the instincts in epilepsy long before the seizure phenomena are added. Indeed, it is demonstrable in earliest childhood whereas the seizure phenomena may be added years after. These defects embrace all the emotional life and the major portion of the so-called character alterations of the frank epileptic in later life, and they are but the innate defects of the childhood writ large. The seizures are but the pronounced maximum expression of the inherent constitution in environmental conflict and the latter are only made plainer as such individuals deteriorate. The nucleus of these defects is in the realm of egoistic tendencies and an extraordinary supersensitiveness. Upon this primary defective makeup the increasing life demands for adjustments are made, and various kinds and degrees of epileptic reaction develop such as moroseness, sullenness, lethargies, extra lability of mood, tantrums and rages, day-dreams of an intense pathologic sort and frequency, mental abstractions with diminished consciousness, and finally, complete breaks with reality as shown in loss of consciousness and convulsions. The real motivation of the epileptic reactions would appear to be best explained on psychologic grounds—that those emotionally defective individuals are too unstable or

*Read before the N. Y. Neurological Society, Jan. 4, 1916.

rigid in adhering to the infantile attitudes and therefore cannot take on adult life, or make its compromises and adaptations, and when this defect of adaptation of the instinctive demands are hidden or repressed, the unconscious cravings are unable to gain satisfaction from reality as it exists, and causes the psychobiological break or loss of consciousness. Then there succeeds a temporary respite or riddance from the daily tension, the psyche regresses to that point or state where it gains peace and harmony. Abundant case studies have proven these contentions. It matters little whether one places the point or degree of regression in the infantile life or even before that. The state sought or found is usually defined as one of complete physical and psychic freedom, a state of harmony and peace. The foregoing in brief is the mechanism of the epileptic reaction in essential epilepsy. The order in which it originates is first the possession of a defective makeup upon which is placed a variety of precipitating causes. The latter are as varied in number and intensity as life itself. If the adaptive demand is largely in the somatic sphere, it is never finally operative in producing an epileptic reaction until it has passed directly or indirectly through the psychologic channels of mental stress and harassment. Pure physical or chemico-toxic states probably never solely generate an essential epilepsy. There must always be a preparedness in the defective makeup, and the psyche is finally involved in the last elaboration of the fit. The latter at any rate is invariably present and can be demonstrated in any given case. In previous studies the fit expression of the disease was held to possess an essential gratification to the libido inasmuch as it had at least a sexually libidinous element. However, later and more complete studies show that this earlier view is too narrow in concept to embrace the full motive of the fit. Continued studies have shown that the larger meaning of the fit in epilepsy is a broadly psychobiological one, of complete riddance of all phases of reality, and at the same time to gain that life release which is comparable to that before consciousness developed, as symbolized in the peace after death, or before birth. While there may be many modifications of this formulation, I believe its main outlines will prove true. I am aware that at least two large groups of critics are in the process of formation—one contends that the views here expressed are not essentially different from those which have already been laid down and that the theory in its general statement is but a *different way of thinking* about the subject; the other contends that the principles are unsupported by clinical facts and that finally the theory is but a mental artefact alike inadequate and unproven. Both classes of critics I must refer to the complete elaboration of the theory and its ample illustration by case analysis which has already been published in part, and also to the large material now in press which I hope will be fully convincing.

Naturally one asks, what advantage does such study afford? First, in prognosis, it enables one to fairly definitely isolate the possibly recoverable cases from those in which there is little or no chance of recovery on the basis of the inherent mental equipment the individual epileptic possesses, the degree of demands he makes on life to gain proper outlet of his general desires, and to what extent he can satisfy them. This fact is of the greatest importance, inasmuch as the majority of all arrested or cured cases of epilepsy are recruited

from the essential epilepsies. The organic epilepsies, once frankly established as such, with the possible exclusion of the depressed fracture and brain tumor cases, are rarely ever arrested. If we may now gain a fair estimate of the degree of maladaptive defect in the particular epileptic, we can begin on a broader and more rational plan of treatment. Opportunity to apply some of the therapeutic principles developed during the study has re-emphasized the importance of some of the old principles of treatment and has suggested other individual helps heretofore somewhat neglected. Obviously in such notes only the broader points of therapeutic suggestions can be outlined. I may say at the outset, one is impressed here as in many another therapeutic field, with the amount of time, pains, and therefore cost the newer views entail. In the first place the method of individual study of the case often takes hours, or even days, to obtain a complete diagnosis upon which to base a proper intelligent treatment. Moreover, when this is even approximately obtained, the amount of care and observation required to get the best results in treatment makes it almost prohibitive to the poor. To meet this latter need only special State institutions are really competent. Then, too, the often parsimonious attitude which the state takes toward properly equipping and maintaining such institutions makes one despair of getting the best results even for the more select and most favorable cases. I know of no state that even approximately meets its obligation in this respect. The greatest demand, moreover, will not be for able and trained physicians, although they are needed badly enough, but for a better trained and efficient nursing class. Leaving out of the question the deteriorated and hopeless epileptics for the time, one may ask, what can be done for the potential epileptic in earliest childhood? We know they are often the despair of the home and school. Such cases need the attention of trained neurologists and psychiatrists. These children do poorly in large groups without individual care. Although institutional schools for neuropathic children are in existence and appear anxious for mild cases for reformation and correction, the potential epileptic with his antisocial tendencies does not come under this designation even though he is devoid of the mildest settings of his disease. These children are ruled against in all the receptive classes in the better grade of homes, and there is a lack of systematic instruction which such children need. It is impossible to strictly classify the types in these homes, as the cost is prohibitive. In my opinion and experience such cases do poorly if grouped with even the better grade of morons in the private home-schools. Then, too, all such children do poorly under the strict discipline which is often laid down in the school-homes. It is next to impossible with the poor class of attendants in these home-schools—who, by the way, are usually fearfully underpaid—to make them comprehend that the whole regimen of wise, gentle, but firm discipline has to be entirely abrogated at certain times—it may be for days or weeks at a stretch when epileptic attacks are imminent or threatened. If the children's departments of general hospitals were properly equipped, or better, if the state insane hospitals had cottage adjuncts near them in the country for the psychopathic class, the problem would be solved. If the potential epileptic children are sent to special sanatoria the nursing staff must be constantly drilled in fundamental principles that the

depressions, day-dreams, lethargies, obstinacies, irritabilities, or even absences—should the latter have already intervened—are not states of laziness, latent or active original sin, but psychopathic traits or symptoms needing special direction and care. Such children should be looked after by pedagogic nurses and constantly supervised by trained psychiatrists.

By the most careful analysis of a large number of epileptics one finds the practical experience of Dewey with normal children is doubly borne out here; the potential epileptic has character defects and bad mental habits which antedate the ordinary school age by several years. It is therefore largely in the realm of the nursery that the training out process must commence. This training largely concerns the proper development of the will, especially in the domain of the reflex, instinctive, ideational, imitative and deliberative responses of the child. Active principles of nursery ethics, too, are in greater demand here than anywhere else, the rhythmic periodicity of automatic life, such as the taking of food, sleep, bath, etc., and the inculcation of patience and tolerance of petty annoyances are very necessary. The degree in which the simple impulsive movements escape repression by the developing will speaks for a degree of a continuance of a neurotic element always to be reckoned with. The importance of a study of these various movements of the neurotic child, and especially the impulsive ones, has been dealt with in another paper already published and can only be mentioned here; suffice it to say that the persistence of these uncommon movements play the chief rôle in the so-called spasmophilic makeup of the potential epileptic child. Disharmony in the development of the will is largely responsible for the moral and ethical cramps of these children as shown in the tantrums. Next the child becomes demanding and stubborn and when its instinctive purposes are further blocked the supersensitiveness is further increased. In the past these psychic conflicts or tantrums have been placed on errors in dentition or so-called latent rickets—whatever that may mean; later in life these physical disorders are regarded as the organic substratum of the so-called spasmophilic constitution. This may be so but that it is an incomplete and one-sided view of the constitutional makeup of such children may be well shown by the kind of therapeutic remedies employed to overcome these defects. Gum lancing as a general practice to relieve the extra nervous tension in the neurotic child has fallen into well deserved disuse; so has the attempt to supply the exact chemical composition of defective bone and neural metabolism. The special compounding of glandular substances to allay bad tempers and supersensitiveness still ranks in practical importance with the seeking of the philosopher's stone or the astrologic signs in the therapeutic wish world of the somatists. In place of these futile efforts we find common sense, or *uncommon* sense, comes to the rescue in the guise of a wise nurse or mother whose real insight into the nature of the difficulty and its correction is a boon to humanity. They seem to comprehend that these neurotic children are slow in adaptation, and that the instincts are slow in being brought under volitional control, even to meet the simplest demands of life. They lessen or make simpler the feedings, give the child more rest and quiet, place him more in the open. The whole regimen is treated with considerateness, gentleness and patience. They strive to gain the

child's confidence, appeal to his developing reason and attempt to employ various methods to sidetrack or substitute simple interests and amusements to avoid the conflicts and still permit the child some expression of its own spontaneous demands for physical and psychic activity. These lay experts seem to instinctively recognize that the extra neurotic tension is pathologic and more often calls for added rest and quiet instead of an active system of overtraining for a neurotic makeup already jaded and irritated. So, gradually, the wise nurse or mother strives to teach adaptation under a policy of quiet unimpassioned play, and rest. Still there must always linger a group of equally neurotic parents, who unwittingly make for an atmosphere of unrest and irritation, and one laments the shrewd dictum of Freud that there are shorter roads for the acquirements of neurotic habits than by inheritance. When both elements are present in the home there must be substituted the "away from home care and training" as previously outlined.

In the light of our present knowledge it is obviously next to impossible to handle any case of epilepsy successfully in the ordinary way, simply by office consultation. The whole training treatment must have a country or small village setting in which the environment can be fully controlled for the patient and reduced to that social level to which the individual case can readily respond without stress. Most of the epileptics possessing nearly the adult level of intellect are but children in their emotional life. It is interesting to note that there is almost a direct ratio of casual relationship between the degree of purely intellectual weakness and the defect of instincts. Wherever the former is severe the latter is very marked also, but in slight impairment of the emotional life the intellect as such may be nearly intact and well developed. How may one judge of the relative suitability of a given environmental setting in a particular case? This is to be determined in a number of ways. The more pronounced cases show bad adaptation by the anxious, troubled character of the dreams, by marked irritable signs, and even more delicately by the lustreless eyes, indolent movements, cessation of spontaneous interest, a falling of the countenance and a pallor. The latter group symptoms are the true psychic indices that the environment does not fit and they should be watched for just as carefully as we formerly estimated the toxic signs which were once judged to be the important ones in drug sedation in epilepsy. It would be an easy matter in successfully treating epilepsy and epileptics in private practice (the principles laid down here are intended mainly for such) if one were to assume but a negative attitude, and simply remove stress from the supersensitive epileptic individual. If that were all, rest in bed in some general hospital might suffice for a time at least; and in point of fact the temporary improvement many epileptics show for short periods of time in such settings but proves how overstrained these patients usually are and how wrongly we have judged their innate capacity for prolonged endurance. So soon as the environment of daily work and play are adjusted, one needs to carefully elaborate a whole system of upbuilding and education to make stronger and more adult the innate defects. To determine this constructive plan the greatest care and patience is necessary on the part of all concerned. The plan that should be ultimately followed will have to extend over several years, and the initial steps should be undertaken

only after one has sized up the individual defects, or, better still, when one has taken full inventory of the good traits and tendencies that are found. For instance, we must find out the main trends of interest and what the various substitutive reactions are which the patient attempts to use and how far they can be amplified. While we may not hope to psychoanalyze the epileptic in its strict sense any more than we may the feeble-minded or precocious dements, the material helps which are furnished by that school afford us the most important guides in the plan of genetic education of epileptics.

In treating the epileptic one assumes more of the paternal guidance and direction of the patient's life such as the undeveloped emotional state of the epileptic demands. The educational and character building require this. The properly developed instincts are not simply distorted, repressed or otherwise held in check as in the psychoneuroses but they are entirely wanting or infantile and must be nurtured and otherwise encouraged to grow. After I had begun to minutely study an ideal group of epileptics and noted the frequent causal relationship between the mood and behavior on the one hand and the occurrence of epileptic reactions on the other, I tried various experiments to see how I could open the patient's eyes to these glaring faults and gain his cooperation. I was surprised to note how readily they understood the simple explanations given (much more readily than many of the relatives) but I was not fully prepared for the naive manner in which the patients proposed to assist at the task. In many instances they looked upon the problem in a very matter-of-fact and, to them, the easiest way. They said, "If we are but to get square with our supersensitiveness to irritation and the resultants of anger, rages, and finally the states of mind where attacks are the only way out, we will simply suppress these irritative states and put a stop to the unconscious demand for fits." Many tried this plan. The apparent working of the scheme was not essentially unlike drug sedation when extra dosage of bromides was employed. Disturbing anxiety dreams then appeared, the sleep was unrestful, and they showed all the signs of physical and mental stress. However, the attacks in most of the patients were steadily lessened; in one who had formerly had several attacks weekly the fits were entirely suppressed for months. But at last the whole plan fell through; some of the patients had grand mal attacks in whom petit mal had formerly existed; others had serial grand mal and one had a mild status; still others had delirious episodes, befogged and anxious states, or day dreams of a hallucinatory character not unlike mild delirium, and some frequently acted as though actually intoxicated by drugs. In brief, direct unrelieved repressive acts on the part of the patient failed as disastrously as gradually increased sedative therapy used to. The whole scheme, however, worked better in the few who would follow a definite guidance and gain some substitutive reaction when the repressive mechanism was applied. The whole observation but furnished additional proof that the fit was but the maximum logical consequence when given the particular type of makeup and instinctive demand which the essential epileptic possesses. None cheated or escaped the logical consequences of fits by a simple repressive remedy. The next attempt was attended by better results—which was in proportion to the degree of their understanding that they could not use the adult normal repressive

measures and be free from epileptic reactions. They then realized that they were placed in a similar position to the schoolboy who cannot make his grade work even by forced draft in study, but must return to that level of classwork where he formerly failed to do good work and where he had omitted the necessary process of learning well his daily lesson. It is absolutely essential in both instances that progress cannot be made until the loss is made good. No essential epileptic will ever recover from his grand mal attacks until he has found that life level to which he can fully adapt or adjust himself. Any therapy that pretends to ignore this basic fact is doomed to failure. Even though this level be attained and seizures cease, it will still remain an unsolved problem as to whether the particular epileptic can take on development to meet a more demanding environment of ordinary everyday life without the return of seizures. The failure in this respect is demonstrated over and over again in so-called cured cases discharged from epileptic colonies. The arrested cases cannot stand the stress of a normal individual without epileptic reactions. It is a pity all physicians do not see this matter in this simple light and make arrangements for a gradual cessation of any successful plan of therapy, which is the method applied to the tuberculous, the insane, and the alcoholic. A follow-up principle of after care in all so-called recovered cases of epilepsy should materially lessen the relapsing cases now so common in the pessimistic literature of our subject.

One often wonders what the mechanism of help is which the epileptic employs in his baffling conflicts. Pains-taking study shows he most frequently takes up deep philosophic study, the reading or chanting of tragic epics, or becomes engrossed in profound religious subjects. When he is blocked in his everyday outlet he goes to a deeper level of tragic thought, or music. This preoccupation seems to lessen the strictly local pain or hurt of a balked desire; it diffuses the poignancy of the feeling over a larger area of his mind; it lessens, as it were, the local intensity of the unsolved conflict. If one will study these "helps" minutely and compare them, it will be found that the common motif in all is death, usually with a triumphal or victorious element at the end; in short, it is an epileptic reaction as characteristic to the makeup of such individuals as the seizures themselves. The content of these tragic words or songs is home, mother, and heaven in about equal proportion, excepting that the latter is a finale of the others in summation.

In some instances epileptics were urged to live on a higher or lower plane than the one upon which they had their most antagonistic conflicts. The latter principle, as might be expected, was the more successful and will be amplified later. As regards the former, some epileptics were taught that they might so plan their lives on a pattern of extra benevolence and ethical behavior as to rise superior to their everyday harassments and gain a sublimation in such acts as would be the equivalent of a discharged affect. Thus music, artistic pursuit, and certain religious practices of the simpler sort were encouraged. But few gained advantages not obtainable by other means. Most failed from the very nature of their defects; that is to say, so many being individualists in pure culture, a higher level was possible of attainment only in those who had lived a full life and in whom the socialization of their personal tendencies was easy and natural. Much of the extra pseudo-benevolence and religious

zeal of deteriorated epileptics are probably but conscious or unconscious attempts of this sort, thus accounting for the remarkable lability of mood and the frequent recourse to the superman attitude. Under the thin exterior of this assumed superior mood lies the intense rage and dislike which easily break through the thin crust of their high adventure and precipitate them into the maelstrom of turmoil, discontent, and unsatisfied longings of their daily existence. The simpler plan of treatment was to encourage the more intellectual epileptics (it was too uninviting and commonplace for the others to seriously enter into this plan) to try the safer course of directing their activities into garden, farm, and shop work; to try to make adaptations of the commonest kind and when they were mastered, to gradually raise the level of adjustment. When this plan can be worked out it is ideal. I may say here that few so-called normal individuals scarcely realize the paucity of associative reactions of which the average essential epileptic is possessed; and upon these few simple reactions life's difficult problems are to be worked out. Can there be any wonder that, given such an inherent makeup, the individual epileptic sees "no way out" and insists with a remarkable soul stubbornness that the particular trend of reality in which his conflict is engrossed must be annihilated, or he must react away from it by tantrums, day dreams and lethargies, or alcoholic indulgences, as in the partly adjusted, or by a psychoneurotic symptom, or even a plain psychotic episode which calls for no less than the annihilation of his own consciousness? As one of my patients said about an altercation difficulty he experienced, "It had to be ended then and there, as though cut off short and sharp," and by an appropriate gesture of the hand he indicated how clean cut the division must be made to enable him to adjust himself to the situation.

I must say that most frequently the individual epileptic does not see his own conflicts, at least not in a conscious sense as the outsider does, and the vividness and justice of his position precludes his taking other than a firm, fixed, and rigid attitude. He has a vague though definite and painful sense of an insuperable irritation from which he reacts by a depression if a fit does not at once occur. The depression is a protective mechanism, in the nature usually of a regression to day dreams interspersed with sighs and petulance or deeper lethargies of apparent obliviousness to his surroundings, yet attended with consciousness or even mild hallucinatory delirious episodes, or by twilight states of mental confusion and disorientation in which he appears benumbed to reality, and finally all ends in a grand mal attack—the maximum of the epileptic reaction.

However, when we come to the manner of treating the extra states of elation and extra well-being which, by the way, are the immediate forerunners of attacks in fully half of all mildly deteriorated epileptics, the principles that should govern our actions are not so simple or easy. In the first place, one needs to know whether the elation is but the thin veneer of a *purposive* mood to meet or to raise the patient out of the "slough of despond," or whether it is really an *unconscious* and *spontaneous* exhibition of outlet activity, a sort of psychic attack in itself in which, as is not infrequently noted, the patient is particularly disoriented and in a hypomanic state. If the former is the case, gentle redirection and a process of teaching the patient to

really square the issue, if possible, on the plane of actual conflict, is the plan to pursue. When this is not possible, perfect rest in bed often works satisfactorily. Certainly any increase of excitement needs to be avoided and that which already exists may be minimized by shortening the contact with the particular setting. This needs to be done with tact and caution, but the wise nurse or attendant can usually find the way out of such difficulties and offer a fair excuse against a repetition of the episode. If the mental exaltation is a slight expression of escape from meeting a previously coercive and unpleasant demand, a direct repression of the state almost invariably causes a severe attack, or an irritable sullenness that lasts for days and from which the patient recovers without an attack apparently with the greatest effort.

In treating individual epileptics one may excavate deeply into the personality, but invariably one comes upon that nuclear substance of character which is adamant and which cannot be removed; this very fact accounts in no small measure for the relapses in arrested cases although they remain free from attacks for years. Any number of my patients say when this deeper and firmer layer is reached, "No, I can never really forgive an injury or insult; to do so would result in the surrender of my personality; if that be required of me I shall have to remain epileptic." However, in psychotherapeutic talks the individual patient is made fully aware of this defect and this seems to rob it of much potentiality for harm.

Finally I wish to state that the more definite psychological approach to the newer study has engendered the demand for a new type of specially trained and educated attendants. A general hospital training is of little service outside of the purely physical care of such patients; the main work is psychiatric in its best sense. One should take on for such work only medically trained attendants with as broad general education and refinement as possible. They should be given regular instructions in which definite case material and set episodes are considered and explained. "Many are called but few are chosen" for continued service in this most difficult field of nursing, where tact, common sense, and an experience of having lived a "full life" seem to be the main basic equipments for the service.

128 EAST SIXTY-FIRST STREET.

USE AND ABUSE OF THE RICE DIET.

BY L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL,
CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

HAVING recently experienced in my own person, for the eighth or tenth time, the remarkable controlling effect of the "rice diet," which I proposed some years ago (MEDICAL RECORD, January 28, 1911), for certain acute inflammatory conditions of the skin, I am constrained to present the subject again briefly, as I do not find that the profession always utilizes it correctly or efficiently.

During the past ten years I have had a large number of patients under this treatment, for a longer or shorter period of time, and have practically never seen it fail to produce the results expected, when properly employed. On the other hand, I have had many patients who reported having been under "rice diet" from other physicians without benefit. I realize that this is often the

case in regard to many remedies and measures advocated, both medical and surgical, which often seem to succeed better in the hands of the originator than in those of others; but there is often a reason for this, in a failure to apply a remedy or measure in suitable cases, or in some error in carrying out particular details properly. The dietary measure which I am advocating is so fundamentally correct, and has proved so invaluable in my hands and in those of very many practitioners from whom I have heard by letter or otherwise, that I would again call attention to it, and try to make clear some practical points in regard to the use and abuse of the rice diet in certain diseases.

It is not necessary here to enter deeply into a consideration of the influence of diet in health and disease, both acute and chronic, as this is recognized widely, although many of the essential details of the same are by no means fully understood: but a few of the principles on which the proposed dietary measures are based may be briefly mentioned.

We all realize that protein is necessary both for the building up and the regeneration of the cells which compose the body; living protoplasm, whether differentiated or not, must contain nitrogen, in addition to its many other component substances. Man seeks this protein largely in the flesh and products of the animal kingdom, and by the gratification of the taste for these substances the system is often so overloaded with nitrogenous elements and their decomposing products that various diseases result.

But the ox and the sheep get their protein from the ground, and man can do the same, and vast numbers of the human race actually do live on vegetarian substances exclusively, or nearly so. There is no need, therefore, to discuss or defend vegetarianism, in theory or practice. The aim of the present writing is to call attention to the fact that under certain conditions it is desirable and profitable to curtail the diet extremely, even along special vegetarian lines, for a longer or shorter period, in order to give the system complete and absolute rest from nitrogenous stimulation, and an efficient opportunity to free itself from excessive and effete stored protein elements which have acted injuriously on some of its tissues.

In my former article, nearly five years ago, I gave very fully my personal experience with the "rice diet" in an agonizing attack of acute vesicobullous eruption on the hands, from which I had suffered for many years in the summer, sometimes even having several attacks in one season. It would sometimes last for weeks, in spite of various treatments suggested by many medical friends, until it was checked so promptly in 1910 by the diet here described. Since that time the attacks in recurring seasons have repeatedly yielded in the same manner to this dietary treatment alone, with absolutely no other measures, internal or external.

In my earlier communication I stated that the cause of the attacks could not be determined; they always have occurred only during the warm months, from June to September, and sometimes have seemed to follow moderate indulgence in strawberries or peaches. I have never been a large meat eater and take no alcoholics, but for many years have had bad kidney action and frequent gouty symptoms, sometimes severe.

My last attack began on July 17, while enjoying a week-end rest at my country home, five days

after returning from an enjoyable trip to the Pacific coast, for a month. The eruption began, as in all other attacks, with a deep itching on the backs and sides of the fingers of the right hand, first toward the roots, leading to a certain amount of rubbing or deep squeezing the tissues. The next day small, deep seated papulo-vesicles appeared, also on the backs of the thumbs, and some itching of the left hand, where papulo-vesicles also developed. Recognizing it as my annual visitor I allowed it to develop for about three days, as I knew it could be controlled by the diet, and then and during the entire attack I employed absolutely no other treatment, internal or external, except pretty free scratching, which gave a certain amount of agonizing pleasure. By July 20 both hands were pretty well affected, with scores or hundreds of deep seated vesicles and considerable general swelling and intolerable itching. I may say that in none of the later attacks have I allowed it to run on to the extent of the one for which I first employed the diet, when there were large blebs between some of the fingers, and a far greater degree of pruritus.

On July 20 I began the "rice diet," and within 48 hours there was marked improvement as to the itching and swelling, with no new lesions, and by the end of five days the attack was virtually at an end; very shortly there was desquamation of some of the vesicles, though many of them simply subsided and were absorbed. I then returned to a plain diet, largely vegetarian, but with very little sweets, and experienced no more trouble. However, from past experience for many years, I can reasonably expect another attack next summer, to be similarly treated, unless I am able to discover some dietary or other cause which can be guarded against. I may add that with many of the attacks there is also some general itching of the body or limbs, with occasional papules, which with scratching could readily develop eczematous lesions, and sometimes did so, until the metabolic disturbance was arrested by the diet.

As many may not have seen the former report of this dietary treatment, brief mention may be made of some of its details, which it is necessary to carry out *exactly*, in order to have good results.

The diet consists exclusively of rice, butter, bread, and water, and nothing else, for each meal, three times a day for a specified time, which may depend upon the nature and severity of the case. The rice is to be well boiled in water, and not too soggy: it is to be taken *hot*, and with only butter and a little salt, not with milk or sugar. It is to be eaten very slowly, and with a fork, not a spoon, and to be thoroughly masticated, in order to secure the full action of the saliva: I commonly tell patients that they are to spend as much or even more time in taking their simple meal, than any of the others do at the table, fully half an hour at least. The white wheat bread should be at least twenty-four hours old, and taken with plenty of butter: it is also to be very well chewed, "fletcherized." Water, hot or cold, but not iced, is to be drunk freely, but not when food is in the mouth. To insure that sufficient water is taken to meet the requirements of the system, and to secure free kidney action, I commonly prescribe also half a pint of hot water one hour before the morning and the evening meal.

The *rationale* of this diet is very simple. For many years my volumetric analyses of the urine have shown me that imperfect or deficient urinary secretion is connected with many diseases of the

skin, and that faulty nitrogenous metabolism appears to be at the bottom of some of them; this is the more apparent in certain acute inflammatory eruptions. It occurred to me, therefore, some years ago, that by relieving the liver and kidneys as far as possible from the intake of exogenous proteins, by excluding nitrogenous elements of diet, the organs would be better able to remove effete nitrogenous material from the system, and the diet was arranged with this end in view. Rice was chosen as being the poorest in protein of all the cereals, and with no purin bodies. White bread was also selected as having on an average only 6.5 per cent. of vegetable protein, almost one-fifth of which escapes absorption. It was directed that the bread should be at least twenty-four hours old, in order to avoid the well-known delay and disturbance of digestion from that which is freshly baked. Butter was given freely on the rice and bread, in order to supply the requisite calories: for a quarter of a pound, which should be consumed each day, represents a total of 894 calories, or nearly one-third of the greatest amount required, and has but a trace of protein. Water alone was given freely, at least five tumblers full daily, as supplying all the needs of the system, without the possible deleterious action of any substances which might be used with it. Milk was avoided on account of its large protein element, and also coffee, tea, and chocolate, as having considerable xanthin products.

As already indicated, this diet is especially valuable in certain acute, inflammatory diseases of the skin, but the more I observe its effect the more I am impressed that its occasional employment may be of service in many disordered states of the system. For acute eczema five days is often sufficient to make a profound impression on the eruption, even without other treatment, internal or external, although it is generally wise to utilize also these to obtain the best results. At the end of five days one can commonly let up on this severe diet, and allow other vegetarian food, continuing the rice diet for one of the meals, breakfast or supper, if possible; or it can be continued longer, and even returned to with an exacerbation of the eruption. In some cases I have, with advantage given the "rice diet" one day in the week, say Friday, over a considerable period of time.

In rare and exceptional instances I have continued the rice diet alone over a considerable length of time. In one case of pretty *general eczema*, with excessive rheumatoid arthritis, in a girl in the New York Skin and Cancer Hospital, the patient was actually kept on the rice diet for three months, using at the same time appropriate internal and external measures. Not only did her extensive subacute general eczema disappear, but her hands, which were at first greatly distorted and firmly flexed, became so free and limber that she moved the fingers readily, remarking, as she held them up and told her story at one of the lectures, "I can play the piano now." She gained ten pounds while under the diet.

In another case, in private practice, a wealthy lady of high position, with *lichen planus*, followed the rice diet perfectly for seven weeks, the period being extended each week at her own request, because of the evident benefit in many directions resulting therefrom. In her case the weight, which was just 200, was reduced to 159 pounds by this and other means, and continues at about that figure. Under this treatment she lost various rheumatic

symptoms and great shortness of breath and felt better than she had for many years.

One lady, aged 45, Mrs. C. L. B., with very general *psoriasis* for 24 years, and an almost crippling rheumatism, actually continued the rice diet, at her own desire, for nearly five months, with a few breaks when she made visits. The results were most remarkable; not only did the psoriasis about disappear without local treatment, but she became entirely freed from her rheumatism and was really a different woman, and came down in weight from 185 to 174 pounds. These are rare cases, though I have others similar on record, and I would by no means often advocate such prolonged severe diet; they are only mentioned to show that even in this country, as well as in China and Japan, rice can not only sustain life but contribute greatly to well-being and the removal of disease.

It is, of course, in acute inflammatory disease of the skin, as in my own case and those reported in my earlier paper, that the striking effect of the rice diet is best seen, and I may say that since adopting this line of treatment the management of this class of affections has been very much more satisfactory to me than before.

A very considerable number of cases of *acute eczema* could be mentioned, of both the erythematous and other forms, which have responded in a remarkably prompt manner. In a rather recent severe case of *erythema multiforme*, in a gentleman, Mr. W. H., aged 64, the eruption improved at once, and all life seemed to leave the bullæ within 48 hours; at the end of five days most of the lesions were dried up, and within ten days they had largely exfoliated. His weight fell from 212¼ to 208¼ pounds, and the urine, which exhibited three times the normal acidity as measured volumetrically, fell to normal.

Some rather interesting notes concerning *asthma* are recorded in certain of my case papers in connection with this rice diet. It is well known that asthma is a not infrequent accompaniment of a number of diseases of the skin, as I showed some time ago (*British Medical Journal*, November 21, 1885), and later observation has confirmed this strongly. One of the physicians attending the lectures at the New York Skin and Cancer Hospital, several years ago, first called my attention to a patient in whom asthma ceased almost at once when the "rice diet" was given for a cutaneous trouble, and would return when it was discontinued, but cease again when the rice diet was taken: this he had observed a number of times. Since that time I have often verified the same in many patients, only that with a continued vegetarian diet and careful medication the asthma remains absent, as well as the eruption.

Realizing the great value of the rice diet, when rightly employed in proper cases, and learning of its occasional apparent failure in the hands of others, I am prompted to make some comments upon errors which I have known to have occurred in its employment, both in my own practice and in that of others. Some of the errors in my cases have been from the misunderstanding or disobedience of directions by patients, while those in the hands of others have often resulted from a failure to give exact directions and to insist on their being carried out perfectly.

In some cases patients have eaten the rice and bread too hurriedly, with a spoon instead of a fork, and without sufficient mastication and insalivation,

and so have suffered from indigestion, as is common among the Chinese, who push the rice rapidly into the mouth with chop-sticks from a bowl held to the lips. Others again will take milk with the rice, as I have repeatedly heard patients say that their doctor had told them to live on a rice and milk diet, which is exactly contrary to the plan advocated. Others have taken coffee or chocolate, and often many other articles in conjunction with the rice diet and defeated its object. Some have followed a correct plan for too short a time, others too long, and I have often known it used in unsuitable cases.

To utilize rightly this valuable adjuvant to the treatment of certain cases of cutaneous disease, not only should the purpose and plan of the diet be accurately grasped, but a correct understanding should be made as to what is desired to be accomplished in each individual case. It is not claimed that this dietary regulation is a cure-all for each and every case; indeed it is but a single, very valuable adjunct, to be conjoined with many appropriate medical measures, and followed by such dietary and medical proceedings as will tend to efface the disease; but, as before stated, when rightly employed in proper cases it is an invaluable aid in practice.

It also takes not a little painstaking and careful explanation to make some patients fully comprehend the matter, so that every detail can be carried out intelligently. When this treatment is first proposed or ordered there is always some remonstrance, and questions are always asked as to other articles of food or drink. But experience has taught me that the best results are obtained by adhering strictly and absolutely to the articles mentioned, certainly for some days, and invariably patients have expressed entire satisfaction with the plan and the effects produced.

The matter of diet does not always receive the attention which it deserves from the medical profession. But with growing knowledge and experience its exceeding great importance in certain conditions of the system is coming to be more and more generally recognized. The present communication is an attempt to introduce more widely a definite line of dietary procedure, in a certain class of cases, which ten years' experience in my own practice and that of many others has demonstrated to be of unusual value.

321 MADISON AVENUE

RADIUM.

A RECOGNITION OF ITS EFFICIENCY AND A PLEA FOR MORE THOROUGH INVESTIGATION.*

By DOUGLAS C. MORIARTY, M.D.

321 MADISON AVENUE

So much has been said concerning radium in the lay press that you may wonder whether it belongs to the armamentarium of the regular or the quack. Personally, I feel that it is a live subject, and that any adverse criticism from the inexperienced unbeliever, that would affect its use where it is indicated, is unfortunate, for it certainly does possess remedial qualities peculiar to itself.

It has been said that "radium is to be considered a force and not a therapeutic measure"; and notwithstanding its physiological action, this expression is certainly suggestive. Radium has been

employed in treating disease for more than ten years, but it is only within the last two or three years that it has been more generally taken up by the profession. A reason for this is, perhaps, that the earliest specimens of radium were disappointing in their action, for it has since developed that they did not contain the quantity of radium that was expected. This was due no doubt to difficulties in producing a pure product commercially.

Radium is a metallic element found in carnotite ore and pitchblende, and first separated by Madame Curie in 1898. It belongs to the strontium-barium group, forms salts with the mineral acids, and is the leading element in the radioactive group whose peculiarity is atomic instability. In the process of disintegration of radium, which never ceases, it loses a portion of its atom and becomes a gas, which is the radium emanation.

Radium emanation can be separated from the radium as fast as it is formed, and a definite amount of emanation is always evolved from a given amount of radium. The emanation from a gram of radium (value \$120,000) multiplied by thirty, would only equal a volume of gas the size of a small pin head. When we realize that few practitioners employ more than 100 to 500 milligrams, and most of us work with success with quantities varying from 50 to 100 milligrams, we get some conception of its wonderful force.

In the so-called decay of radium, a particle of radium splits into alpha rays and emanation; this emanation in turn splits into alpha rays and secondary deposit, and from the splitting of this secondary product come the other two classes of rays, known as beta and gamma. If this splitting or decay, which is constantly going on, occurs in radium that is sealed, the emanation is enmeshed in the radium itself, and gives rise to the mechanism of general radiation and the liberation of energy. This is the so-called "ageing" of radium, freshly prepared radium being comparatively inert until the process has advanced thus far. As there are no gamma rays until the third decay product, the maximum of the gamma rays, under these conditions, does not develop for a month.

If, however, the radium is open, or in solution, the emanation is liberated as such, and may be used by inhalation or in solution as activated water. Thus, in any case, the action of radium depends upon emanation, which is its radioactivity. In the one case, as in a tube, there is a uniform activity of the rays from the splitting and successive products; in the other case the emanation is introduced into the body, where the splitting of the rays goes on with the same identical liberation of rays and energy as if it were sealed. Thus the therapeutic value of radium may be roughly divided into external and internal administration.

The three kinds of rays, to which the names alpha, beta and gamma have been given, have well-defined characteristics and differences. Technically speaking, alpha rays are not rays at all, but are positively charged atoms of helium, with a weight four times that of an atom of hydrogen. They are liberated with an explosive force, and travel 12,000 miles a second. The energy of their liberation accounts largely for the heat of radium, and the force of their bombardment for the injuries to the tissues, such as superficial irritation, as well as burns of varying degree.

The beta rays are also not rays at all, but a negatively charged stream of electrons.

*Read by invitation before the Glens Falls Medical Society of New York, December 17, 1915.

The gamma rays are not particulate matter, but a vibration of ether, similar to ordinary light. They do not polarize, pass straight by a magnet, and are not deflected by a prism.

In the use of radium externally it is necessary that the rays should be filtered to avoid superficial irritation and burns. By this we mean simply that the passage of certain rays must be obstructed by the interposition of some material or space that will absorb or stop the rays that are developed which we do not want to use. Alpha rays, being particles all traveling the same distance at the same time, are stopped by a slight obstacle, such as a sheet of paper. Beta rays show different degrees of penetration, being divided into soft, medium, and hard.

If one makes space the filter for these various rays, alpha rays are cut off by a distance equal to 3 cm. of air; beta rays, by about three times that amount; while gamma rays would reach a distance of 100 meters and still affect the electroscope, or travel 3 meters, penetrate a man, and cause a fluorescence beyond him. The ratio of penetration of these rays may be expressed by 1; 100; 10,000.

For the alpha and soft beta rays, one may make simple filters of lead, paper, rubber, or mica. Metals, however, furnish the common filters for the medium and hard beta and gamma rays; silver, aluminum, lead, brass, and more recently gold and platinum, are employed. One centimeter of lead screens the hard beta rays completely; gamma rays need 5 cm. of lead for what is practically complete absorption, although a small fraction will still be left with 10 cm. We thus vary the quality of the rays by filtration. Without filtration, there are 90 alpha particles to nine beta and one gamma ray. Under strong filtration, 600,000 total rays are reduced to 5,000 (gamma) rays.

Mention should be made of still another class of rays which are created when a filter of lead is used in the application of radium; they are called secondary rays, are very irritating, and can be screened by rubber tissue of varying thicknesses.

After the nature of the rays and the kind and amount of filtration have been determined, the third factor in radiation is the density of the tissue to be radiated. A knowledge of all three facts is essential in practice; in fact, they absolutely control and determine the results of radium treatment, when it is used externally, and when these factors are not well understood, it is easy to account for the failures and disappointments in its external use. It is my experience that radium is always going to do *something*, but success in its use will be achieved only after we have learned how to use it.

In considering the use of radium, we will find that the alpha rays must in the main be rejected therapeutically. Their discharge has been called "the most intense liberation of power in nature." *Kinetic energy* is their chief characteristic. As has been said, they account for the heat of radium, their chemical energy is shown in catalysis, and the rays are irritating and destructive to normal tissue. Soft beta rays are in much the same category; but the hardest beta rays which are much more penetrating, are similar in effect on pathological tissue to gamma rays. In gamma rays, it is agreed, we have the most useful therapeutic agent of radium as they will penetrate a great distance, though as we have said, their number is relatively small. Our problem is to get the greatest amount of these rays in any given place. This will depend upon the intensity (amount of radium used), the manner of

filtration, and the period or time of exposure. The intensity of an application is greatly augmented by what is termed "cross-firing;" this is simply the focusing of the gamma rays from several sources upon a given district; the burying of a tube will also increase its efficiency many times, because all the rays will thus become engaged; while if it lies upon the surface this is not the case, as only the rays emitted in the direction of the object can be effectual.

Gamma rays are shown to have a predilection for pathological cells, in proportion to their youth, embryonic state, or degree of development; the quantity of radium employed should be at least sufficient to affect the normal tissue. Young connective tissue, in the vicinity of the application, may be observed multiplying and developing vigorously. This is the essence of the favorable action of radium on morbid tissue; normal tissue elements are stimulated, while morbid ones wither and are gone. All observers have seen the wonderful power of radium to destroy growths of a simple and intermediate nature, from warts to non-infiltrating carcinoma. Large cell growths are simply "blown to pieces." New growths differ considerably as to their degree of resistance. Epitheliomata require larger doses than some other morphological tissue. The nearer the surface of the body the new growths are, the easier can they be destroyed, whether benign or malignant. Growths of the mucous membrane of the mouth require large doses and are quite difficult to cure. The effect of radium extends only to the depth of a fraction over an inch; therefore, a large mass to be attacked successfully must be carefully plotted with extensive direct radiation. If possible, a tube of radium should be placed in the tumor mass for a cross-fire. Applicators in the form of needles are here useful. The results of treatment may be complicated by an erythema, or even a severe burning, and by extensive edema. This is usually due to ineffective screening, or too long an application, where a large dose seems imperative. Toxemia from absorption, following prolonged treatment where there is no drainage, must be borne in mind, for I am convinced that massive radiation was a factor in a fatal termination of one of my cases. Burns *per se* are not material if the desired result has been accomplished at the time they occur. They are ordinarily superficial, not very painful, and heal slowly. But if the further local application of this particular field is to be continued, then the early irritation or congestion must be recognized and radium application be discontinued for a time, otherwise sensitization of the skin will result and further treatment must be delayed indefinitely. After the area is once sensitized I find it necessary to renew treatment with much smaller dosage.

As I have said, all these mentioned factors enter into the problem of the successful use of radium. In addition to the knowledge of the character of the rays, the technique of filtration, the time of exposure, etc., we must take into consideration the amount which it is necessary to use, its form and shape, and the location and position of the application. We must also consider the susceptibility of the tissue involved, its pathology, the varying degrees of resistance of the different normal and abnormal tissue cells, as well as other chemical, physiological, and biological factors, all of which must be understood before the therapeutic value of this element can be fully determined. Until experience has given us more knowledge, the results of treat-

ment must, in many cases, be unsatisfactory; not because radium is not capable of doing the things we would like, but because we have not as yet learned how best to make it always do what we want it to.

Radium administered internally has an action startling in many ways. Here it is used either by inhaling the emanation, drinking the activated waters, or water in which radium salts have been dissolved, or by intravenous injections; all of these methods are effective in their proper sphere.

The physiological action of radium sounds not unlike a fairy tale. It often increases the red blood count $\frac{1}{4}$ of a million in forty-eight hours, and also the hemoglobin markedly in a short time. It stimulates all cell life, particularly that of the enzymes, thus aiding and improving metabolism. It increases the elimination of carbon dioxide, urea, and uric acid, and in addition is said to keep the latter in solution in the blood. It diminishes the viscosity of the blood and greatly increases the quantity of urine secreted. It stimulates and increases the appetite, and aids digestion by activating the digestive ferments. It dilates the blood vessels, through the excitation of the vasomotor nerves. Its action in anemia is little short of marvelous, it relieves the pain and local manifestations of gout promptly, and also the pains of neuritis. It lowers blood pressure almost so surely as you administer it. It is a prompt and powerful tonic and stimulant. In larger doses it often produces a *decided reaction*, causing headache, nausea, lassitude, and general body discomfort. The cases in which this reaction occurs are thought surely to receive benefit from its use. No toxic or lasting ill effects have been reported.

The dosage of radium is quite as important internally as externally. Internal dosage does not seem to have been definitely determined, though we are daily getting a more clear conception as to what can be expected from various dosage. The men who use infinitesimal doses, and there are a goodly number of them, are quite as enthusiastic over the effect secured as are those who use it in larger doses; and none of them hesitates to express his opinion of its therapeutic value. The varying degrees of chronicity and the amount of metabolic derangement seem to be controlling factors as regards the amount of radium emanation to be given. Frequently, we meet patients who exhibit a well marked susceptibility to radium and who react to extremely small dosage. Ordinarily, I classify my cardiovascular-nephritic cases as requiring low dosage and my arthritis cases as requiring high dosage. Each case must be judged as it stands and after treatment is inaugurated its course must be regulated by carefully checked laboratory findings.

I first became interested in radium in 1912, when the National Bureau of Mines announced that some of our mineral springs at Saratoga contained radium in solution, and that others were activated by radium emanations. The Bureau of Mines, in making this announcement, furnished me with the explanation of the value of our mineral spring waters, which to me had always been unexplainable. In a paper written in 1908 I stated that the results I had observed from the use of the waters were surprising, and could not, to my mind, be accounted for by a knowledge of the chemical analysis of the waters. I stated that the natural waters at Saratoga presented unusual therapeutic properties which are peculiar to themselves and not presented by artificial waters made after the analyses of the chemists, and gave

as a reason that I believed that the combination of bases of acid radicals in nature's laboratory under pressure and heat did not result in the theoretical formula believed and accepted by the chemists who made the analyses. I am now convinced these peculiar therapeutic properties are due to radium influences. We are not in a position to announce at this time any data relating to the limitations and efficiency of radium as a catalyzer. Suffice it to say that it is a property of marvelous importance.

For years I have had unusual results from our mineral spring waters, when their use was associated with a carefully directed personal regimen, in cases of high blood pressure, gout, obscure neuralgic pain, arthritis, etc., the reasons for which were not clear to my mind, until I became familiar with the physiological action of radium in various amounts and knew that it was contained in our waters. With those who would refer all the benefit derived by these patients to the regulated regimen, and a protein-free diet, I would disagree. Radium, even in such small doses as occur in our Saratoga waters, is a wonderful synergist to metabolism and when it is administered, proteins do not have to be so restricted, neither do nitrates have to be used to control the high blood pressure of arteriosclerosis. As we increase the amount of radium by direct administration, either by intravenous method or by mouth, definite biochemical manifestations are noted which give us reason to accept radium as an active therapeutic force.

A word concerning arteriosclerosis may not be amiss. The early symptoms of this degenerative process are seldom appreciated, because they have not been associated with the diagnosis of the later manifestations. The late symptoms are often confused with atheroma of the arteries, the latter being due to advancing years and senility, while arteriosclerosis need not of necessity be a senile condition. The early symptoms of arteriosclerosis are nervousness, irritability, insomnia, and a general breaking-down in a young person; these are caused by continuous over-work, excitement, speculating, the use of alcohol, gormandizing—in fact, the abuse of nature in every way. A large number of these individuals soon or later, develop the late symptoms, which are characterized as cardiovascular, cardiorenal, and myocardial degeneration, with the concomitant high blood pressure; this latter symptom being very popular, is the bugbear of the public generally and a meal ticket for the profession particularly. It would seem to me that this symptom is not correctly interpreted or well understood, and it occurs to me that physicians seldom differentiate between a high compensating pressure and a true hypertension. In other words, the etiology and pathology of arteriosclerosis are entirely ignored, and the one ambition seems to be the relief of this one symptom, *i.e.* high blood pressure. In my experience, radium never fails to control this symptom when it is intelligently administered. I have treated these cases for many years in my summer practice by regulating the diet, amount of exercise, rest, etc., with the internal and external use of our mineral waters; and usually the symptoms are controlled to a marked degree, without the use of nitrates; and this result, I now believe, is due to the radium contained in our mineral spring waters. Following up this effect I have found that with increased radium dosage I can secure more permanent results in my cardiovascular cases.

In the direct application of soluble radium salts,

my experience extends only over a period of about fifteen months. During this time I have used it in emanation, in activated water, the dissolved salts intravenously, and radium solutions by mouth in about sixty cases. My results have been without exception amazing; so much so that those uninformed concerning radium, or those who are skeptical as to its value, would surely question my conclusions.

I appreciate the fact that the number of cases is too few, and the period since instituting the radium treatment too short for the results to be accepted as cures. Yet they serve to emphasize the statement that I have made that radium is a potent therapeutic measure, when the quantity of radium that should be used in a given case, and the conditions controlling its use are correctly interpreted.

I have found that when a patient is to be treated by radioactive waters or by inhalations, the best results are obtained by commencing the treatment with the injection intravenously of at least 25 micrograms of radium chloride; the idea is to give a goodly quantity to act in the body in the beginning, and to maintain the saturation by replacing the elimination of the dissolved salts, by the waters or by the inhalation of emanation.

The amount of activated water that a patient will accept I have found will vary from 10,000 to 100,000 mache units daily. I have usually administered it in four doses, so divided that three are given one-half hour after meals and the fourth on retiring.

In all cases in which I have used radium internally, I have preceded its use by making a red blood count, noting the hemoglobin and the blood pressure, and making a urinary examination. I have observed that without exception there has been an increase in the red blood cells of from 50,000 to 250,000 in ninety-six hours. Invariably the hemoglobin has been increased. When radium is well borne, it is a marked tonic and stimulant; the appetite has been markedly improved, as have been the digestive processes, and the patient experiences the sense of well being.

In one case of arthritis deformans which I here cite as a type, the patient, a school teacher, 50 years old, was practically a helpless cripple. Her hands were terribly deformed, the joints large and fingers thrown out at an angle; in fact, we had a typical picture of this condition. Her knees and ankles were swollen, the motion in all joints limited, she could not close her jaws tightly, had difficulty in masticating her food, the tissues of her back were in a tumefied condition, and she was in constant pain. She was given an intravenous injection of 50 micrograms of radium chloride and then continued to use radium by drinking the activated water. After a period of four months the pain has subsided, she walks without limping, and closes her hands, and, as she says, bites a thread if she wishes to when sewing. I might mention in this particular case, that her blood pressure at the time of taking the injection was 240, the blood count 3,500,000 and the hemoglobin 80 per cent. Twenty-four hours after its administration the blood pressure was down to 180. Ninety-six hours after the treatment, the red blood count was 5,200,000, the hemoglobin 90 per cent. and blood pressure 185. The quantity of urine had increased from 30 to 60 ounces daily.

I have had eight cases of neuritis or myalgia that had existed for months, resisting all treatment, that have been relieved by the use of radioactive waters with a single intravenous injection at the beginning of the radium treatment.

I have had seven cases of nephritis with albumin, casts, headache, loss of appetite, shortness of breath, and precordial distress—one in particular with the headache so strongly marked that the patient was incapacitated. All cleared up so that the patients, to use their own statements, which seemed general, "feel like a new being." I have had two cases of gout which under emanation treatment were entirely relieved of active symptoms.

My results from the local application of radium in malignant and benign growths have been equally startling. I have been permitted to use the element to date in some fifty-three cases, which present conditions varying from carcinoma of the breast to uterine fibroids. As a result I am greatly impressed with the value of radium in gynecological practice.

The large majority of these cases gave entirely successful results—in malignant cases futures are to be considered. Radium exerts a destructive influence on the malignant mass in a manner more humane than any other known agent after the knife has been withheld. It controls pain, hemorrhage, and odor. It frequently gives a hope to the hopeless that I would not withhold. I esteem radium as an invaluable adjunct to surgery and I feel we are fast gaining a better conception as to its efficiency. My recent experience from the use of radium in all of its forms has been so uniformly promising that I actually hesitate to report it and I would not wonder should clinicians question the accuracy of my primary observations and ultimate results. I assure you my convictions that evidence enthusiasm have developed against my prejudices. Personally, I feel that we should endeavor to foster in every manner any investigation that shall have as its purpose a thorough study of this wonderful element. We should be able to look to some of our great research laboratories for real data. The day is past where we will proclaim radium and radioactive substances as agencies of mystery with no special merit. The little we are able to unfold tells a different story. The problem is how soon are we to know and understand its marvelous energy?

511 BROADWAY.

CONCERNING RUBBER GLOVES.*

By ROBERT T. MORRIS, M.D.,

NEW YORK.

PROFESSOR OF SURGERY NEW YORK POST-GRADUATE MEDICAL SCHOOL.

SOME years ago I published an article condemning the indiscriminate use of rubber gloves. This brought out favorable comment from a number of the older expert surgeons, and it called up a great deal of unfavorable criticism from men who had been trained to believe that rubber gloves should be employed in all operative surgical work. Perhaps it is now time for me to state clearly certain views which are the outcome of more extensive experience.

First, let us take up the matter of principles. According to the fundamental ideas of the third or pathological era of surgery, the operator was to remove bacteria and their products most thoroughly from any infected area. This called for a degree of technical work which represented progress, but nevertheless often proved injurious to the patient. Furthermore, it was frequently unnecessary. We

*A paper read at the meeting of the Medical Union, New York, January 25, 1916.

are now passing into the fourth or physiological era of surgery.

The main idea about which our new methods are grouped consists in giving the patient the mildest attack of surgery which will suffice for turning the tide of battle between bacterium and organic cell. It is the idea of conserving the patient's energies and turning him over to himself as expeditiously as possible—in other words, giving him "home rule." Most surgeons cannot introduce their nicest manual technique when wearing gloves.

The methods of the fourth era of surgery include the idea of the least possible degree of handling of sentient tissues, and the shortest incisions which will suffice for accomplishing an object without jeopardizing any of the patient's interests. Furthermore, rapid work is desirable in order to avoid sending prolonged destructive influence into the patient's centers of consciousness, which are never wholly asleep, no matter what degree of anesthesia may be employed. Regarding this, Dr. T. L. Bennett says that the best surgeon is the one who acts all of the while as though he were afraid of waking the patient up.

In order to follow the principles of this fourth era of surgery, one needs to depend very largely upon the sense of touch. We often have to work by touch in a class of cases in which a phrase "expose all of the pathology" belongs to the third or pathological era of surgery, now passing. It is better not to expose all of the patient's pathology in many of these cases in which we already know what that pathology is, and what the patient will be able to do with his repair machinery if he is not shocked too deeply.

In some cases a large incision and tedious technical ideal work will allow many more bacteria to fall into a wound from the air than would be carried in by well prepared surgical hands.

This matter of careful preparation of surgical hands is sometimes neglected by men who put too much confidence in their rubber gloves. I would not advocate any idea which jeopardized the patient's interests. On this basis I made at one time a quiet examination of hospital records of a number of surgeons who worked without gloves, and of a number who worked with gloves. Some of us who depend upon careful preparation of our hands had fewer cases of infection than were recorded against other operators who used rubber gloves in all of their operative work. In only one instance did a surgeon who wears rubber gloves continuously have better results than my own, and he is a better surgeon than I am, anyway.

For hand preparation I have depended for some years upon one of the chemical substances which does not coagulate albumin, and which leaves the skin of the hands soft, and free from that epithelial injury which follows the use of bichloride of mercury. There is doubtless a difference between hands of various surgeons in this respect. Hands which are continually moist, indicating some chronic toxic influence (chiefly from the colon, according to Lane) may carry more active colonies of latent bacteria in their epithelium than would be found in the epithelium of the hands of men in perfect health. We have laid too much stress upon the need for the employment of germicides in hand preparation, when a powerful antiseptic, not a germicide, might cause less injury to the protoplasm of the epithelium of the surgeon's hands.

The advantages of working by the sense of touch

in preference to the sense of sight in certain cases has been recognized by surgeons since the earliest days of surgical history. The sense of touch is dulled by the best of gloves.

The operator in a case of perforated ulcer of the stomach, working by sense of touch, may introduce drains down to the region of perforation and complete his preliminary operation in three or four minutes of time, leaving subsequent details for a secondary operation.

In typhoid perforation, or in cases for drainage of the fluid belonging to parenteral anaerobes in typhoid hemorrhage, the entire operation from first incision to last suture may sometimes be done in seconds instead of minutes where one is working by the sense of touch.

When removing firmly adherent organs like oviducts in cases of pyosalpinx, or the appendix in acute infective cases, work may be done through short incisions by aid of the sense of touch very rapidly and accurately. Long incisions naturally predispose to the development of post-operative hernia, if the patient has the luck to live and face that danger.

For cases in which we need to be particular about scarring, one will often work to advantage through incisions which could not be employed if the sense of sight were our chief dependence.

On the other hand, rubber gloves may be worn to advantage in almost all of the so-called "external operations," such as amputations or excisions, or hernia, in fact I need not enumerate. Surgeons there be who are not well trained in the principles of asepsis or of antisepsis, yet who are doing a great deal of operating. For such operators I would prescribe the employment of rubber gloves under all circumstances."

The question of wearing rubber gloves was first brought forth actively at a time when I was most deeply engaged in forwarding the principles of the fourth era of surgery, and for that reason my stand against the indiscriminate use of gloves may have been made with more emphasis than would be placed upon the subject at the present time, when very thin flexible gloves are to be obtained from the manufacturers. Rubber gloves which were put upon the market at first were comparatively thick and cumbersome.

Excepting in abdominal work rubber gloves give a certain percentage of results in their favor, even with the most expert operators, provided that very thin gloves are used. Personally I prefer the ones which are made in such a way that the knuckles of the operator are left free, without the necessity for putting the rubber particularly upon the stretch over the knuckles. There is thus less interference with the sense of touch under these circumstances.

There is no need for bringing up the question of desirability of rubber gloves for use in obstetric work or in various examinations, or for protection of the surgeon in some fields of work in which the advantages are obvious.

Improvements in rubber gloves have been so marked that I do not now have the feeling that was engendered when I saw dangerously bungling work done by men who were wearing thick gloves. At that time it was evident that younger men who were being trained to wear gloves in all operative work would never develop the fine sense of touch belonging to the surgeons of a past school.

A BROADER VIEW OF TABES DORSALIS.*

BY FRANK R. STARKEY, M.D.,

PHILADELPHIA, PA.

THE development of our knowledge of tabes has been a matter of slow evolution since Duchenne casually alluded to the frequency of syphilis and demonstrated involvement of the posterior columns of the cord in tabes. The cause was a matter of dispute. Leyden declared chill to be the most common and probably the only cause. Duchenne was of much the same opinion, but he and Wunderlich pointed to overexertion, fatigue, and sexual excess as probable causes. Wunderlich also suggested that concussion of the spine might be a causative factor. Erb was the first to lay especial stress upon syphilis as the essential cause of tabes, and he was ably supported by Fournier among the French, and Möbius and his colleagues of Leipsic sustained him fully in this view. Möbius, with much emphasis, declared: "Without syphilis there is no tabes." Erb substantiated his opinions by a long series of tables of cases showing that syphilis was undoubtedly present in a vast majority, if not in all persons who developed tabes, but he believed it was a parasyphilitic disease due to the influence of toxins rather than the actual invasion of the cord by the syphilitic germ. As late as 1911 Oppenheim gave voice to the following: "We are by no means justified in regarding syphilis as the *conditio sine qua non* of tabes, as Brassard, Babinski, and others do. Tabes is further not a syphilitic disease in the pathologico-anatomical sense. The pathological changes have nothing in common with the well-known lesions of visceral syphilis, although Erb does not admit it. It is nevertheless conceivable that syphilitic cachexia is the result of poisonous chemical substances produced in the organism which bring about simple degeneration in certain portions of the nervous system. Those suffering from tabes seldom present any constitutional sign of syphilis." So it will be seen that at no time has there been an unanimity of opinion concerning the etiology or pathology of tabes, and that some of our most learned neurologists and pathologists clung to views that we now believe to be entirely untenable. The discovery of the spirochete in the cord tissues by Noguchi and Moore in 1913 placed an entirely different light on the whole matter, and it is now generally accepted that in tabes there is an actual invasion of the tissues of the cord by the spirochete. We have, however, adhered to the histological picture of a cross section of the cord in our conception of this disease, and accepted the teachings of our forefathers, who considered it solely a systemic degeneration of the posterior columns.

We must now go beyond this very circumscribed view, for it by no means gives us an ample conception of tabes in its broader sense. In view of our present knowledge of the glands of internal secretion and of the autonomic and sympathetic nervous systems and the relation of the endocrinous glands thereto, we are now able to explain many mysterious phenomena of tabes which could not be accounted for solely by degeneration of the posterior columns of the cord. The nuclei of the vegetative system are so intimately associated both in the brain and the cord with those of the sensorimotor system that it is impossible to separate them. The autonomic and sympathetic nervous systems are un-

questionably under the control of the glands of internal secretion, and if we study their embryonic origin we will find that the origin of the chromaffin system, the sympathetic nervous system, and autonomic and central nervous systems is closely associated. The reproductive organs are also closely allied in this relation.

It may be well for us to pause for a moment and view the distribution of the autonomicosympathetic system (for the sake of brevity counting them as one). The autonomic supplies the muscles of the iris, ciliary muscle, and orbital muscle (disturbance of this would account for Argyll-Robertson pupil), heart, blood vessels of the mucous membranes of the head, walls of the gut from the mouth to the descending colon, also the gastric glands, liver, and pancreas. The sympathetic, from first thoracic to second lumbar, supplies muscles, glands, and vessels of the skin, vessels of the gut from mouth to rectum, blood-vessels of the lungs, abdominal viscera, arteries, skeletal muscles, spleen, urethra, and internal generative organs. The autonomic, from second to fourth sacral, supplies arteries of rectum, anus, and external generative organs, also walls of bladder and descending colon. A lesion here would account for bladder phenomena, impotency, incontinence of urine and feces, so common in tabes. Other frequent findings in tabes which can be accounted for by disturbance of the autonomicosympathetic system are muscular atrophy, which in tabes does not follow the course of any particular nerve, but occurs in large groups of muscles, frequently unilateral tabetic arthropathies (Charcot joint), perforating ulcer of the foot, or of the mucous membrane, occasionally with gangrene, somatic disturbances of general nutrition, disturbances of nutrition of hair, skin, and nails, and aortic disease, manifesting itself in insufficiency or aneurysm. Cardiac crises and vascular crises have been described by Pal; these crises frequently resemble angina pectoris—a feeling of oppression about the heart, with arrhythmia, bradycardia, tachycardia, bradypnea, and glycosuria, common in association with paralysis of the vagus in pituitary involvements and in tabes. Oppenheim describes a case of tabes which was marked by unilateral total paralysis of the vagus. When we remember that the vagus supplies the pharynx, larynx, lungs, heart, esophagus, abdomen, intestines, and the fundus of the external auditory meatus, we will at once be able to account for the analgesia of the pharynx, laryngospasm, esophagospasm, intestinal and gastric spasticity, and disturbances of the auditory tract. With the autonomic and sympathetic, like the glands of internal secretion, there is a normal equilibrium maintained in health, but in the case of the autonomic and sympathetic this balance is established by a normal antagonism between them. Stimulation of one abolishes the action of the other. The adrenal is the natural stimulator of the sympathetic, and although we cannot definitely establish it as yet, the pituitary and sexual glands are probably the natural stimulants of the autonomic for vagatonias are conspicuous in sexual neurasthenics and at the climacteric. Although the fibers of these two systems are so closely related that it is impossible to differentiate them anatomically, we can readily influence each system separately by the use of adrenalin for the sympathetic or pilocarpine, atropine, muscarine, or a number of other vegetable substances for the autonomic.

We may summarize the symptoms which we com-

*Address delivered before the Wayne County Medical Society, Detroit, Mich., October 18, 1915.

monly find in disturbance of the glands of internal secretion, the autonomicosympathetic system, and tabes, as follows: Disturbances of nutrition involving skin, hair, nails; blue, swollen, or gangrenous skin or mucous membrane; atrophy of large groups of muscles, not following the course of any particular nerve; perforating ulcer of the hand or foot; profuse sweating; neurasthenia; arrhythmia, and other disturbances of the circulatory apparatus; disturbances of respiration; glycosuria; visceral crises; analgesia of pharynx; pharyngeal, laryngeal, esophageal, and pylorospasm; spasticity of stomach or intestines; splanchnic congestion; hyperalgesia of the abdomen; Argyll-Robertson pupil, and disturbances of the sexual organs. We must not expect to find all of these symptoms or signs of involvement of the glands of internal secretion and of the sympathetico-autonomic system in each individual case, any more than we expect to find all of the classical features of typhoid fever in every case of that disease, but a sufficient number of these signs are constantly present in all cases to prove the point at issue.

Arthropathies can be most rationally accounted for as a trophic disturbance through the sympathetic. There is absolutely nothing to differentiate microscopically the cord of a case of tabes showing arthropathies from one in which they are not present, and there is certainly nothing in common between the Charcot joint and ordinary syphilitic arthritis, nor is there the slightest pathological difference in the cord of a tabetic patient with Argyll-Robertson pupil from one with normal pupil, yet we know positively that the Argyll-Robertson pupil may be absent in tabes, and that lesion of the sympathetic will produce it. Eloesser produced Charcot joint by traumatizing a segment whose posterior roots had been cut.

I believe that we should consider the treatment of tabes as separate from syphilis, not attempting to deny the syphilogenesis of the disease, and this in my opinion can be accomplished best by organotherapy. (See Starkey: "Glands of Life.") I think it is not always wise to treat the patient for syphilis, but rather, in selected cases, to treat the tabes separately. I wish to make it very clear that I do not make the slightest claim that organotherapy can cure syphilis, but tabes is not syphilis. It does, however, seem to act as a sensitizer and increases the phagocytosis or formation of antibodies, the patient's resistance is increased and he responds more promptly to antisyphilitic treatment when used in conjunction with organotherapy. I want to emphasize that in many cases of tabes where the syphilis seems to be dormant or quiescent it is better to allow the syphilis to sleep rather than to arouse it to a state of activity by antisyphilitic treatment. Such cases when treated by salvarsan or even the mercurials frequently show marked exacerbations, due to the setting free of enormous quantities of toxins or the liberation of the spirochetes which have been encysted, and do not improve under further antisyphilitic treatment. Since the advent of salvarsan and the vigorous treatment of the primary stage of syphilis incident thereto the percentage ofluetics showing early nervous involvement has been distinctly increased. Our experience seems to show that when the disease is attacked in a vigorous manner in the early stages and the secondary stage prevented or aborted, the liability to early and severe nervous phenomena is increased. It would seem that where the infection spends itself by severe secondary

phenomena its virulence is attenuated and the liability to involvement of the nervous system is distinctly lessened. The German aphorism; "syphilis does not die but only sleeps," I believe to be applicable here, and when it is in a sleeping or quiescent state it is decidedly safer to let it sleep in these old cases. I have at present under my care a gentleman, 76 years of age, who contracted syphilis fifty years ago and received the rather indifferent treatment in vogue at that time. He has shown no manifestations of syphilis whatever since, until three years ago, when slight numbness of the feet with paresthesia over part of the thoracic region and a rather marked myosis developed. He has absence of knee jerk and a two plus Wassermann. This myosis may be due to his age. He shows absolutely no other signs of syphilis, and I believe that to institute antisyphilitic treatment in this case would be a grave error.

The question of why a very small percentage of those infected with syphilis acquire tabes, while the vast majority do not, has been a puzzling one for many years and numerous very ingenious attempts to explain it have been made. I believe that it can be most rationally explained by assuming a constitutional inferiority involving primarily the glands of internal secretion, the pituitary in particular, and the consequent perversion of its secretion which is poured directly into the cerebrospinal fluid. It may be that when this gland is involved and its secretion perverted it acts as an irritant to the tissues of the cord, making them vulnerable to the invasion of the spirochete, or again the sympathetico-autonomic system, which presides over nutrition, may be originally involved in these patients and their vulnerability thus increased. This seems to be more rational than to believe that a special organism exists which creates tabes only. Certain strains of germs have been shown to have selective predilection for certain tissues, but this can be developed only by passing them through a number of individuals with a definite disease, and this particular phenomenon has never been demonstrated with the *Spirochaeta pallida*. It has also been shown that certain prostitutes leave numerous victims of tabes in their wake, but these instances are so rare as to be of little assistance in answering this question.

The following rather typical cases are cited not for the purpose of showing the results of treatment, but solely to illustrate the connection between the glands of internal secretion and tabes.

CASE I.—Female, aged 45, married, one child. Family history: unimportant. Previous history: unimportant, except scarlet fever in childhood. Denies venereal disease. Seven years ago first noticed difficulty in walking in dark and numbness of feet; ataxia gradually developed until patient was unable to walk without assistance, then arthropathies (Charcot joint) developed in knees, which necessitated the use of crutches; for past three years unable to stand unassisted, compelled to use wheel chair or crutches, complains of stuffy feeling, shortness of breath. Examination: medium height, quite obese, brown hair, gray eyes, puffy face, myxedematous appearance, unable to open eyes widely, palpebral fissure, narrow, slight external squint of right eye, skin and hair dry and harsh, subcutaneous tissue firm to pressure, entire body, especially legs, swollen in appearance but does not pit on pressure, marked hyperextension of knees making it impossible to stand, temperature 98.6°, pulse 65, abdominal and thoracic viscera normal, Argyll-Robertson pupil, loss of knee jerk, blood pressure 120 mm. Wassermann three plus. This patient presents a typical picture of thyroid insufficiency. An orthopedic appliance for one leg was prescribed and organotherapy instituted. At the end of twenty days was able to stand and walk unassisted with hands behind back. The swollen appearance of body greatly lessened, legs

so reduced in size, readjustment of brace was necessary, crutches and wheel chair entirely dispensed with.

CASE II.—Male, aged, 55, chemist. Family history: father died of diabetes, otherwise negative. Previous history: ordinary diseases of childhood, chancre twenty years ago, first noticed difficulty in walking ten years ago, a tendency to fall, lightning pains in extremities and gastric crises, diplopia then developed, was treated by ordinary methods for syphilis and received ten injections of salvarsan which caused diplopia to disappear and lessened gastric crises for a time. These pains, however, returned with usual severity. Examination: fairly well developed male, 5 feet 10 inches, dark complexion, coarse hair, prominent eyes, large lips, high cheek bones, large jaw, angular conformation of body, prominent acral parts, large hands and feet, skin cold and clammy to touch, perspires profusely on slightest exertion, decidedly neurasthenic, tendency to muscular atrophy in large groups of muscles in arms, shoulders, back and legs, very ataxic, Argyll-Robertson pupil, knee jerk absent, examination of thorax elicits aortic insufficiency otherwise negative, dullness in percussion over entire abdomen, splanchnic congestion (evidence of vagotonia), temperature 97.5°, pulse 60, blood pressure 100 mm. Wassermann negative. I believe this patient to represent hypopituitarism and hypothyroidism secondary to hyperpituitarism and hyperthyroidism. This is further borne out by the prompt response to organotherapy. Within one week patient's temperature was normal, pulse 72, blood pressure 120 mm. and within two weeks was able to walk a chalk line without perceptible ataxia. Continued to improve under further treatment.

CASE III.—Man, aged 45, occupation, retired, married nine years, no children. Family history: negative. Previous history: ordinary diseases of childhood, including scarlet fever and diphtheria, syphilis eighteen years ago, treated vigorously, did not develop secondary eruption, first noticed tingling sensation in feet nine years ago which extended to legs and arms, walking became difficult one year later and manifested difficulty in starting urine about this time. Present condition: walks with cane and assistance of nurse, decidedly ataxic, complains bitterly of lightning pains in legs, arms, and stomach, partial incontinence of urine and feces, entirely impotent. Examination: Tall, light complexion, prominent eyes, wide palpebral fissure, rather slender, delicate features, tapering fingers, very little hair on body, small bones, fine hair, skin cold and clammy, complains of cold, perspires easily, complains of choking in attempting to drink due to pharyngeal spasm, decidedly neurasthenic, pulse 70, blood pressure 90 mm., temperature 98°, Argyll-Robertson pupil, loss of knee jerk. This patient is undoubtedly one of hypopituitarism of the second classification. I saw him only twice and was unable to make a complete study or note results of treatment.

CASE IV.—Male, aged 60, occupation, brewer. Family history, unimportant. Previous history, ordinary diseases of childhood, typhoid fever at eighteen, denies specific infection; first noticed diplopia twelve years ago, then uncertainty in walking, especially in the dark, pains in arms, legs, and various parts of the body, treated for rheumatism, developed girdle sensation, vision became impaired six years ago, now totally blind, walks with wide base but little ataxia, however, makes very little attempt to walk unassisted. Examination: Height 5 feet 8 inches, weight 200 pounds, decidedly stout, dark complexion, coarse hair, shaggy eyebrows, heavy moustache, thick leathery skin, pudgy face, heavy lips, constantly in profuse perspiration, legs swollen and blue, skin cold and clammy to touch; examination of chest reveals small aneurysm of ascending arch of aorta, temperature 97.8°, pulse 60, blood pressure 121 mm., knee jerk absent, areas of anesthesia in mammary region and on inner side of thighs and legs below knees, also some perineal anesthesia, neurasthenic, complains of insomnia, is of a positive stubborn, disposition, very intractable, difficult to manage. Under organotherapy pains reduced, neurasthenia much improved, sweating lessened, insomnia disappeared. Discontinued treatment at end of ten days. I would classify this patient as thyroid insufficiency secondary to hyperthyroidism.

Many of the most troublesome symptoms of tabes can be clearly accounted for by involvement of the autonomicosympathetic system, and bearing in mind the governing influence of the glands of in-

ternal secretion over this system, the gratifying results obtained in this disease by organotherapy are easily understood.

The cardinal points in organotherapy are; first, select the glands from uncastrated animals; second, administer by intramuscular injection; third, use in combination as they occur in nature. The adrenal can be omitted in ordinary therapeutic measures, as it is represented by the pituitary. The dosage is to be worked out in each case.

There is no constant relation between the length of time tabes has existed and the amount of destruction found in the cord or severity of symptoms; neither is the severity of symptoms an always accurate index of the extent of the lesion in the cord. I have seen fulminating cases in which the patient became bed-ridden within a year after development of first subjective symptoms and other cases in which, after more than twenty years from onset of symptoms, the progress had been so inconsiderable as to but slightly inconvenience the patient. I have sections of cords showing but slight destruction of the posterior columns in which the ataxia, root symptoms, and bladder and rectal involvement were very marked early in the disease, and later improved spontaneously. The improvement in these cases may be due to sound cells taking on new functions. That an actual regeneration of cord tissue can take place is a matter of dispute, although it is certainly frequent in other nerve tissue.

CORNER WALNUT AND SEVENTEENTH STREETS.

A SIGN IN FRACTURE OF THE PELVIS.

BY G. P. COOPERNAIL, M.D.,

BEDFORD, N. Y.

IN practically all cases of fracture of the pelvis there will appear in from one to three days a more or less extensive ecchymosis of the perineum and scrotum in men, perineum and labia in women. In cases of not very extensive fractures of the crest of the ilium this sign may not be present.

In fractures of the pubic portion of the pelvic ring (which is the most common fracture), invariably one will find ecchymosis of perineum and scrotum inside of three days.

The diagnosis of fractures of the pelvis in many cases is far from easy. Localized tenderness at the seat of fracture may be the only sign present at the time of injury. Crepitus, the cardinal sign in so many fractures of other bones, is often absent, and in most cases there is comparatively little or no displacement.

This sign does not compare with the x-ray in diagnosis of fractures of the pelvis, but it will be found to be of interest, and will be a help to make a diagnosis before using the x-ray.

Ecchymosis of the perineum will be found present in a much larger percentage of cases of pelvic fractures than is ecchymosis behind the ear and under the conjunctiva in cases of fracture of the base of the skull (Battle's sign), to which it is analogous.

I have not been able to find this sign mentioned in medical literature.

Mortality from Wild Animals and Snakes in British India.—The recently issued Government resolution on wild animals reports 1,745 persons killed during the past year by wild animals in British India, an increase of 9 per cent. on the last year's casualties. Tigers caused 646 deaths. Snake-bites were responsible for 22,894 deaths, an increase of 1,124 over the previous year's figures.—*The Lancet*.

LARYNGEAL TUBERCULOSIS.*

By MALCOLM F. LENT, M.D.,

LAKE KUSHAQUA, N. Y.

MEDICAL DIRECTOR, STONY WOLD SANATORIUM

WHILE it would be impossible for me to touch on all the phases of tuberculosis of the larynx, I would like to bring before you some of the points which have seemed interesting to us at Stony Wold.

This complication is the most frequent one occurring in pulmonary tuberculosis. Statistics have shown that actual tuberculous involvement occurs in the larynx in fifty per cent. of all cases of pulmonary tuberculosis coming to autopsy, and clinically laryngeal tuberculosis has been demonstrated by various laryngologists in from fifteen to thirty per cent. of their cases. It occurs most frequently between the ages of 20 and 40 (rarely during childhood), and is more often found in men in the ratio of three to two. In our series of 1598 cases of pulmonary tuberculosis admitted to the sanatorium since 1903 we have found that the laryngeal complication was present in 286, or 18 per cent. This is a rather low percentage as compared with the statistics of some observers, but probably can be accounted for by the fact that only women and young girls are treated in this institution.

There has been diversity of opinion as to the mode in which tubercle bacilli gain access to the laryngeal tissues. We may consider that primary infection is extremely rare. There have been a few cases reported, and in those the point could be well raised whether they were primary or not. Was there not some tuberculous focus elsewhere in the body that was not demonstrated, such as a latent pulmonary, gland, or lymphatic disease? It is practically impossible to prove the existence of primary tuberculosis of the larynx without autopsy.

There are three ways in which the bacilli reach the larynx in the secondary infections, namely, by the lymphatics, by the blood-vessels, and by infection from the sputum itself lodging on an already inflamed and perhaps eroded epithelium. These, though, are problems still under discussion, but the weight of evidence probably lies with the lymphatics as the means by which the bacilli are carried to the larynx. As proof of this, generally the laryngeal involvement occurs on the same side as the pulmonary lesion, or in cases of bilateral disease in the lungs, is generally found on the side of the more extensive involvement. The text-books describe the various stages of the disease as anemia, congestion, infiltration, and lastly, ulceration. There is, however, no sharp line of demarcation of one stage from another, and I wish to state that we have observed congestion in the early cases more frequently than general anemia. It has been the general opinion throughout the country, except, perhaps, among specialists and men doing pulmonary work, that each stage must necessarily follow the other in the order above named with a fatal termination, but such is not always the case. I have observed in a number of cases that infiltration does not go on to the ulcerative stage.

I wish now to consider the subjective symptoms. The early symptoms would be, perhaps, slight changes in voice, or a sense of vocal fatigue; slight tickling or dryness of the throat; frequent clearing of the throat; perhaps a temporary loss of voice, and later in advanced cases pain and dysphagia.

*Read at a meeting of the Franklin Co. Medical Society, Dec. 14, 1915.

While I do not wish to underestimate the value of subjective symptoms in some cases, I want to point out how very misleading they are, as there can be an extensive laryngeal involvement with comparatively few and mild symptoms. We have been able to watch this time and again. The dysphagia that we are all familiar with is rather rare, unless there is an acute swelling or ulceration on the epiglottis, which is pinched by the act of deglutition, or an ulcer on the pharyngeal surface of one or both arytenoids, or on the aryteno-epiglottic fold, or on the pharyngeal surface of the posterior commissure. We must not wait for the so-called text-book symptoms occurring in the last stages of the disease to diagnose laryngeal tuberculosis—I mean the hollow, rasping cough, aphonia, and dysphagia, characterized by regurgitation of food and severe pain in the throat radiating to both ears.

If the diagnosis of laryngeal tuberculosis were made early, before extensive destruction of the deeper structures of the larynx took place, the outlook would not be considered hopeless, as I believe is the opinion among a large percentage of medical men to-day. The early cases can be much more easily cured, and often an examination of the larynx will enable us to make a diagnosis of a hitherto unsuspected pulmonary lesion. As it is true the early diagnosis of pulmonary tuberculosis with suitable treatment gives favorable results, so is it true concerning laryngeal tuberculosis. The following case illustrates the point well:

In 1906 a physician in New York City consulted a well-known laryngologist, complaining only of a slight cough and hoarseness. After making the examination, the throat specialist told the physician rather tersely that he was full of tubercle bacilli. What was the laryngeal picture that led him to make the diagnosis? Simply a hyperemia of the posterior end of the left vocal cord. The physician consulted a lung specialist, who found that he had an infiltration at the left apex. I had the good fortune to study this larynx, and in six months' time the left vocal cord had returned to normal, and to-day this same physician is practising and is apparently perfectly well. There are numerous similar cases which could be cited.

The diagnosis in many cases requires but a few moments; in others several days of patient observation will be necessary. A unilateral swelling or hyperemia of either one of the vocal cords, more frequently the posterior portion, or one of the ventricular bands is very suggestive of a tuberculous infection. A tuberculous infiltration of the posterior commissure is probably found more often than in any other part of the larynx. A partial paralysis of one vocal cord is quite commonly found in early pulmonary disease, caused by pressure on the recurrent laryngeal nerve either by enlarged bronchial glands or by an infiltration at the apex of the lung.

We have found, in detecting small, superficial ulcerations, a Zeiss special mirror magnifying twice, very useful, but this is not to be recommended in doing routine work.

The areas which we have found involved in order of frequency are as follows: Posterior commissure, vocal cords, arytenoid cartilages, ventricular bands, aryteno-epiglottic folds, epiglottis, subglottic space. We would have to differentiate from catarrhal laryngitis, syphilis, malignant and benign growths, rarely lupus. Simple catarrhal laryngitis occurs in a large percentage of tuberculous patients, is

generally bilateral, in contradistinction to the congestion of a vocal cord or a ventricular band, in a beginning tuberculous laryngitis. The mucous membrane of the posterior commissure in chronic catarrhal laryngitis may be thickened, but this is not nearly so prominent and is smoother than in a tuberculous infiltration. Without going further into the differential diagnosis we must not forget that syphilis and tuberculosis may coexist, and the outcome in these cases is decidedly unfavorable.

The outlook for recovery, a comparatively few years ago, was held to be absolutely hopeless. The average length of life was placed at from two and a half to three and a half years at the most. I think the average duration of life in most cases could be more correctly stated as ten years. Each case must necessarily be considered individually. Some cases even heal spontaneously. An infiltration in the posterior commissure is very prone to heal. The swelling, if small, may be absorbed entirely, or may, if larger, remain stationary for years and not pass on to the ulcerative stage. This is probably due to a fibrous tissue hyperplasia. An infiltration in the ventricular band generally gives no symptoms; this may overlap the underlying true cord and remain stationary for years. We have observed several cases of this kind retract and disappear entirely.

In involvements of the epiglottis and arytenoids the prognosis is much more serious on account of the inability of the patient to take even liquid food, but even in these areas it is possible for superficial ulcerations to become healed, and even an extensive involvement may become arrested for a long time. Tuberculous laryngitis, developing during pregnancy, is nearly always fatal.

The treatment and management of these cases is often sadly neglected. The patients should be given all the advantages to be derived by a change of climate, with the hope of bettering the general condition and increasing their power of resistance, which generally follows a sojourn in an altitude resort. Usually the laryngeal complication improves in direct proportion to the improvement of the general condition and to that of the lungs, but this is not always true, as we have seen cases in which the pulmonary involvement was arrested or quiescent, whereas the laryngeal complication grew steadily worse. The so-called resistance of the patient is an important factor, but not the least important is the supervision, the determination, and the stamina of the patient.

In reference to local treatment we certainly have no drug that is specific, but the few things that we can do are important. First and foremost is vocal rest, and by this I do not mean simply to tell the patients not to talk, but to see that our instructions are carried out. I do not believe that it is enough to limit them to whispering, but to insist on their carrying on their communications entirely by writing. It is not necessary to enforce these strict measures in cases of involvement of the epiglottis, but only where the areas involved must be under more or less muscular strain during phonation, such as an infiltration of a vocal cord or an arytenoid cartilage. Prohibition of alcohol, smoking, or any other irritating influence must be insisted upon.

In making local applications, here again we are obliged to consider the individual case. In some, cleansing the larynx by an alkaline spray followed by vaporized oily sprays of camphor and menthol is all that is indicated, and in some cases the intra-

laryngeal application of lactic acid, formalin or argyrol will often aid in promoting cicatrization of a previously sluggish ulcer. The electrical cautery has been coming again in favor during the past few years and is in the hands of a few of the laryngologists, in selected cases, giving excellent results. In the far advanced cases with marked dysphagia, the use of cocaine in the larynx should be avoided, if possible. Relief from suffering may be obtained by the insufflation of powdered orthoform within the larynx, a short time before eating. A tablet of orthoform gr. 1, menthol gr. 1/10, and camphor gr. 1/10, dissolved on the tongue also gives temporary relief in these cases.

In pulmonary tuberculosis we all know wonderfully good work is being accomplished everywhere, but laryngeal tuberculosis is absolutely neglected in most instances. Laryngologists are rarely consulted by the patients themselves until they are in the last stages of the disease. The general practitioners are the men who must make the diagnosis early, if they will but take the time and trouble to do it. Any physician can, with a little practice, become skilled in the use of the laryngoscope. I do not wish to leave the impression that laryngeal tuberculosis is not a grave complication, but I do want to make a plea for routine laryngeal examinations, with the hope of making earlier diagnoses, and thereby increasing the percentage of healed lesions in a disease heretofore considered by most authorities absolutely fatal.

A SIMPLE TONSIL OPERATION UNDER LOCAL ANESTHESIA.*

BY HAROLD HAYS, M.D., F.A.C.S.,

NEW YORK

ASSISTANT SURGEON IN OTOLGY, NEW YORK EYE AND EAR INFIRMARY; ASSISTANT LARYNGOLOGIST, CITY HOSPITAL AND NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

1. *Anesthesia.* The tonsillar regions, pharyngeal wall, palate, uvula (posteriorly and anteriorly) are sprayed with equal parts of 1 per cent. cocaine solution and adrenalin (1/1000). A few moments later the parts are well applicated with a 10 per cent. solution of cocaine (Fig. 1).

The anterior and posterior pillars of the tonsils are then injected with a one-quarter of 1 per cent. solution of cocaine, to which is added an equal part of adrenalin (1/1000). The injection is made with a special needle attached to an ordinary universal syringe (Fig. 3). Twenty to thirty minims of solution are injected, starting from the superior portion of the anterior pillar and going down. One must be sure to have some of the infiltrate reach the plica triangularis. Three to four injections are given in the anterior pillar, one or two in the posterior pillar. The injection is really a Schleich infiltration anesthesia (Fig. 2).

2. As the main attachment of the tonsil is to the anterior pillar, particularly at the plica triangularis (Fig. 1), the next step in the operation is the dissection of the tonsil capsule from the anterior pillar. This is readily accomplished by depressing the tongue firmly and inserting the author's double-bladed knife (Fig. 4) below the plica and then working it upward toward the uvula until the anterior pillar is free from the tonsil capsule.

*Presented to the Laryngological Section, N. Y. Academy of Medicine, Dec. 10, 1915.

3. Instead of using a forceps on the tonsil, the author has devised a modified aneurysm needle (Fig. 5), which does the work admirably. The in-

(Fig. 6). A knot unites the free ends so that it cannot slip out.

4. The tonsil is now separated from its remaining

FIG. 2.—Method of injecting the anterior pillar with cocaine and adrenalin.

strument is very sharply pointed and has two openings through which a piece of stout cord or string can be threaded (silk cuts through the tissues too readily and should not be used). This instrument, suitably threaded, should be brought through the deepest part of the tonsil from below upward (Fig.

attachments with a Hurd tonsil separator and with the index finger (Fig. 7). The separation will frequently sever the anterior attachment, but often too great force is necessary to free the posterior pillar. If the index finger is inserted into the opening made between the anterior pillar and the tonsil, traction

6) and one end of the string caught with a forceps and brought out of the tonsil. We thus see that when the instrument is withdrawn the string is through the tonsil and can be used as a retractor

being exerted on the string-retractor, the tonsil can readily be stripped from its bed with very little traumatism (Fig. 8).

There is seldom any bleeding when the operation

is performed as above described. A large space is left between the pillars which heals readily in the course of a few days. If one desires to assist the

CORRECTION OF DEPRESSED NASAL DEFORMITY BY THE TRANSPLANTATION OF CONJOINED BONE AND CARTILAGE.*

BY WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.

NEW YORK.

THIS fourteen-year-old girl is from my clinic in Gouverneur Hospital. She fell, striking on her nose, when she was five years of age. As she grew older a marked depression developed below the ends of the nasal bones. There is no obstruction to nasal breathing. The girl has always been healthy and strong, and there is neither history nor suspicion of syphilis.

Examination shows a depressed deformity affecting the cartilaginous dorsum of the nose. There is no resistance on palpation at this point, showing that the tissues are not supported by the septum. The cartilaginous septum is neither crushed nor is it deflected, but is undeveloped, apparently having ceased to grow after the injury; it does not extend high enough to support the nasal bridge. The case shows well the results of the absence of

FIG. 1 Before operation

the developmental power usually exerted by a normal septum.

The details of my operation for correcting this deformity have been previously given to this Section. Briefly it consists in resecting a portion of the ninth rib about two inches in length, two-thirds of the section being rib and one-third costal cartilage, the periosteum being preserved on its outer surface. This fragment is then split in its transverse diameter and the outer half trimmed to suit the deformity.

After the left nasal cavity has been freed of its vibrissæ, thoroughly cleansed, and painted with tincture of iodine, an incision is made with a small spatula-shaped knife in the roof of the cavity at a point corresponding to the interval between the upper and lower lateral cartilages. Through this the tissues over the bridge of the nose are elevated, and a cut is made into the frontal bone just above the frontonasal spine. With a small knife, the blade of which is curved upon itself, a pocket is made toward the tip of the nose.

The transplant is then introduced, the upper bony

*Read before the Laryngological Section of the N. Y. Academy of Medicine January 26, 1916.

end being tucked under the periosteum over the nasofrontal process and in close contact with the bone. The tip of the nose is then pulled downward and the lower cartilaginous end of the transplant is slipped into its pocket near the nasal tip. The edges of the incision naturally fall together, and no suture is used to close the wound. The nasal cavity is packed with vaseline gauze for twenty-four hours. In this case the operation was performed on Dec. 7, 1915.

This method of operating has the following advantages over the external route: (1) There is no external scar. (2) The swelling of the tissues is less, as the opening in the subcutaneous sac is at

FIG. 2.—After operation.

the lowest point, thus favoring drainage. (3) The wound is less liable to infection, as the normal nasal secretions inhibit if they do not destroy bacterial growths. (4) The use of conjoined bone and cartilage enables one to repair the bony ridge with bone and the cartilaginous bridge with cartilage; thus reproducing as nearly as possible normal conditions, and preserving the flexibility of the nasal tip.

The results in the cases that I have done by this method have been entirely satisfactory.

TWO LABORATORY SUGGESTIONS.

By GEO. B. LAKE, M.D.,

CAPTAIN MEDICAL CORPS, U. S. ARMY

An Eye Shade for Microscopic Work.—The man who is doing nothing but laboratory work, and sits at his microscope for several hours every day, soon learns to disregard the images registered by the eye which is not in use, although it is wide open; but those whose microscopic work is only one of many duties often have difficulty in cultivating this faculty, and the muscular strain necessary to keep the idle eye closed is very tiring.

As a help to the large class of occasional laboratory workers the screen or shade shown in the figure may prove as welcome as it has to the writer. (See Figure.)

Cut the shade out of very stiff cardboard, making the hole of such a size as to fit snugly around the eyepiece of the microscope; remove the eyepiece, force the shade down over the upper end of the tube and replace the ocular.

The shade may be readily adjusted to the most satisfactory position.

"Toning" Wright's Stain.—All laboratory workers know that Wright's stain does not keep well, so that old preparations frequently fail to make stains which will show the features required.

Being in possession of a very limited quantity of this stain, on one occasion I found that it had gone bad and set to work to see if it could be improved.

The following suggestion, made by an enlisted man of the hospital corps, who was assisting me in the laboratory proved satisfactory.

When the smears were stained too blue (red cells lilac or violet instead of red) a very small drop of

acetic or hydrochloric acid was added to 100 c.c. of the stain. When stained too red (leucocytes, especially lymphocytes, lilac or pinkish) a very small drop of normal sodium hydrate solution was added to 100 c.c. of stain.

By adding very minute quantities of acid or alkali with a glass rod, and staining experimental slides after each such addition, the exact tone desired may be produced in a short time.

FORT OGLETHORPE, GA.

Medicolegal Notes.

Authority to Practice—"Severing" Tissues Defined.—In an appeal from a conviction of violation of section 17 of the act of the California Legislature of 1913 for the regulation of the practice of medicine and surgery, the defendant contended that section 8 of the act was unconstitutional and void in that it was an unrestricted invasion of the art of osteopathy, chiropractic, and mechanotherapy, as it prevented practitioners of these systems of the healing art from practising their profession "without in any manner severing or penetrating any of the tissues of the human body." Assuming, the court said, as asserted by the defendant, that members of such schools, by practising, as they do, by manipulation and adjustment, are constantly and continuously severing tissues of human beings, and that the practice of their art is impossible without it, still it is very plain from a reading of the whole section that the word "sever," as therein used, means a severance by cutting. Under one form of certificate the holders thereof, as provided in the act, may not only prescribe and use drugs, but may also sever and penetrate with a knife the tissues of human beings. The holders of other certificates are drugless practitioners, and they may not prescribe or use drugs, nor may they operate with a knife or in that way sever or penetrate the tissues of human beings, except that they may sever the umbilical cord. Sections 9 and 10 of the act, providing that to obtain a license the applicant must be a graduate of some college approved by the board of medical examiners, was held not to be unconstitutional as vesting the board with arbitrary power.—*People v. Tom J. Chong* (Cal.), 151 Pac. 553.

Statute Requiring Certificate to Practise Held Unconstitutional.—The Iowa statute providing that it shall be a misdemeanor for any person to practise medicine, surgery, or obstetrics in the State without having first obtained and filed for record a certificate from the State board of medical examiners, is held not to be repugnant to the Bill of Rights, the Constitution of the United States, or the State Constitution.—*State v. McAninch*, Iowa Supreme Court, 154 N. W. 399.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

See fourth page following reading matter for Rates of Subscription and Information for Contributors and Subscribers.

New York, March 4, 1916.

THE SEMICENTENNIAL OF THE MEDICAL RECORD.

THE MEDICAL RECORD was fifty years old the first of this month. Half a century is not much to speak of in the life of a nation, nor is it anything to brag of in that of an individual. In medical journalism, however, it is somewhat of an achievement, though to our venerable and highly esteemed Boston contemporary and the even more venerable and equally esteemed *American Journal of the Medical Sciences* we may still look like a youngster. The *New York Medical Journal* is but one year older, so we were really boys together and the respect we entertain for our fellow worker in the medicoliterary field is inspired not by its age but by its merits. Throughout the fifty years of its existence the MEDICAL RECORD has had the same publishers and but two editors, the first one guiding its course for thirty-eight years. As we have never before been so old as we are now, and never expect to be so young again, our readers will perhaps pardon us if our talk takes a personal turn, and if we seem to say overmuch regarding our accomplishments during the past half century let it be put down to the garrulousness of age—or the egoism of youth.

The first issue of this journal was published March 1, 1866. It was a paper of 24 pages, and contained original articles, hospital reports, society reports, descriptions of new instruments, reviews, abstracts of articles from foreign journals, news, and editorial articles. The contributors of original articles, whose portraits, with that of the first editor, to whose genius this journal owes its existence, we publish in this number, were William H. Van Buren, Gurdon Buck, Austin Flint, Alfred C. Post, and T. Gaillard Thomas, of this city, and E. Williams of Cincinnati—a goodly list of great names, showing that from the first the MEDICAL RECORD has been a favored channel through which the leaders of the profession have addressed their colleagues. In his salutatory Dr. Shrady set forth the aim of the new periodical. "Its object," he wrote, "will be to present to the profession a faithful record of the existing state of medical science in every one of its many departments; and, as it is more especially intended to meet the wants of the general practitioner, all the different articles published in its columns will be thoroughly practical in their character. With a wide field and ample facilities for

working it up, we earnestly hope to fulfill to the letter this part of our design, thus making the RECORD worthy of the countenance and support of the profession, a journal to which they may at all times look for information, instruction, and edification."

How well the MEDICAL RECORD has kept this promise we ought perhaps in modesty to leave to others to say. Few of our readers, however, have lived through this half century—the most wonderful and most glorious in the history of medicine—and they may not realize what great events and discoveries it has fallen to the lot of this journal to chronicle. In another column we present a brief sketch of the progress of medicine in our own time, all of which has been recorded in these pages, and much of which we were the first to bring to the notice of American physicians. Among these were Lister's method of antiseptics, a discovery nearly contemporaneous with the birth of the MEDICAL RECORD; Koch's discovery of the tubercle bacillus and that of tuberculin; the employment of cocaine in eye surgery; the Roentgen rays; the discovery of the antitoxin of tetanus and that of diphtheria, and many more. A partial list of these prior announcements will be found elsewhere in this issue. They are mentioned not in a spirit of boastfulness, but as an evidence that the MEDICAL RECORD has always endeavored to live up to its name as a medical newspaper as well as a repository of scientific communications from the leaders of medical thought in America.

As we have before quoted from Dr. Shrady's salutatory, it will be permissible to repeat what he wrote at the end of the first year, when reviewing what had been accomplished during the first twelve-month; this we do in the hope that our readers may regard it as a fitting review of the work of the first half century, also. "We have the gratification," he said, "of assuring our patrons that the RECORD is in every way a success. We are in no danger of shocking our modesty by such an assertion, as its claims for favor have rested upon the aid which its numerous friends by their valuable contributions, kind suggestions, and judicious criticisms have given it. In its management it has been our aim to be strictly impartial, and every consideration has been second to that of ministering to the more pressing wants of the daily practitioner. If we have in any respect failed in this endeavor, it has been more an error of the head than of the heart. Our duties to our readers render it incumbent upon us to furnish the best available material, in the shape of contributions, from the most competent men. It is pleasant for us to think that in this regard, at least, we have discharged these obligations."

OPPOSITION TO THE HEALTH INSURANCE BILL.

THE action taken on Monday of this week by the Medical Society of the County of New York in recording its disapproval of the Mills bill, now before the State Legislature, for compulsory health insurance would seem to have been ill-timed and ill-advised. There was no reason for hasty action. The bill is still in the preliminary stage and every-

one knows that it has little chance of being enacted into a law during the present session of the Legislature. By hastily adopting the report of the committee on legislation and refusing to postpone final action until the next meeting, the County Society has not only been unnecessarily hasty, but has also affronted its own special committee appointed to study the subject. The Mills bill has several undesirable features which can easily be eliminated, but the fire of criticism of the committee on legislation of the County Society was directed not so much against the faults of commission as against those of omission. The bill touches upon only a few of the medico-economic problems involved in the administration of social health insurance. The committee which had charge of drafting the bill purposely avoided the inclusion of details of organization in order that they might be written in by the representatives of medical societies. In condemning the bill because it did not include the sections left open for medical advice, the county society defeated its own usefulness in the matter and failed to serve those very interests for the safeguarding of which it thought it was acting. Many of the points raised in the report of the committee on legislation were well taken and should be included in the final draft of the bill before it becomes a law. Nobody seems to question that. The committee would have served the society better if, instead of urging the action taken last Monday, they had submitted their manifold suggestions for the careful consideration of the special committee. As it is, they have put the County Society into a position which it will have soon to abandon if it would be constructively helpful. And furthermore, as we have said before, the Society has unnecessarily and tactlessly offended the special committee called for by the comitia minora to study the subject in a calm and judicial manner.

Whether one likes it or not, social health insurance is bound to come sooner or later, and it behooves the medical profession to meet this condition with dignity and to insist firmly and without heat that a measure designed to benefit and strengthen the social fabric of the community should deal fairly with the physician on whom its eventual success must of necessity depend. Blind condemnation will lead nowhere and may bring about a repetition of the humiliating experiences suffered by the medical profession in some of the European countries. It is our duty to see to it that our laws relating to health insurance shall not only be improvements over those of England and Germany, but also be more considerate of the economic interests of the medical profession. But we should go about this important task with a well-balanced temper and with a determination based on hard thinking and complete mastery of the subject.

PHYLOGENETIC REACTIONS OF FEAR.

THE fireside puss, because of her ancestry and ours, arouses a shuddering reaction of terror in many individuals. Indeed, this fear holds so prominent a place among the phobias that afflict mankind that G. Stanley Hall gave it a special place in his study of fear. (*Amer. Journ. of Psychology*, Vol. XXV.,

Nos. 2 and 3.) "The Felidæ mnemes and engrams in our psychophysis organization" form one important group, he holds, of registration of ancestral behavior mechanisms, which are ours by inheritance, but which we are still only learning to place under the higher psychic control. Fear probably arises, he says, all but simultaneously with the first automatic response to the pleasure-pain stimulus. It is its immediate product. Henceforth it is anticipation of a repetition of the pain based on the former experience. The ameba reacted with a sudden protoplasmic withdrawal from adverse stimulation and established this anticipatory memory, which has developed into the complexity and diversity of present day fear.

It is a far cry from this beginning even to the dawn of human history, but through these ages these reactionary mechanisms were deeply laid. Hall directs our attention to the diversifying and intensifying of these when the complexities of human life are arising but call as yet only for the more direct automatic response. Our primitive forefathers must needs be constantly on the alert, and gradual transformation of mode of life and change of environment but increased the presence of threatening foes.

The slithery serpent was the chief enemy of his arboreal life. His foes were multiplied when at last he trod the earth in upright manhood. The ubiquitous and fierce Felidæ, with other beasts of prey, the greed and violence of his fellow man, tropical thunder and lightning kept him in a continuous fear of attack, robbery, rape, violence of all sorts. His own unguided imagination supplied besides all the terrors of the supernatural. Emergencies arose quickly. They were in concrete form and called for direct modes of reaction. It was necessary that blood pressure should be increased, respiration quickened, muscles rendered tense, metabolism accelerated through thyroid activity, glycogen multiplied, sweat glands stimulated; in brief, that the whole automatic activity of the nervous system should establish itself in ineffaceable reactions. The race would not have survived had it not been so. It is still, therefore, these basic activities that spring forth at the call of fear. Our relative helplessness before them conditions a special phobia of its own in a fear of shock. We dread the sudden revelation to ourselves and others of the presence and power of the primitive in us.

We cannot question such a phylogenetic foundation to our reaction to fear. Somewhat specious, possibly, may be the more descriptive outline of the origin of our specific phobias, like that of the domestic cat. Our psychic inheritance may not descend to us in such distinct entities. We share with our earliest ancestors, however, something more fundamental and dynamic. The intensity of energy, which motivated humanity no less than now, stimulated desire first of all—at least, so the new school claims. Fear, according to those who credit the new psychology, arises only out of frustrated desire. The energy balked in its attainment gives rise to anxiety. Illuminating studies in symbolism and its notable employment in neurotic thinking, they say, reveal that the various objects

of fear are not shadowy survivals of the past, but just as real in the wish objects they symbolize as were the terrors of that time. These actually blocked the path of primitive man; at the same time they were symbols for him, too, of desires becoming gradually unattainable. As such, may be, they manifest their fear-provoking power to-day.

OLD AGE IN RELATION TO CANCER.

IN the vexed subject of the etiology of cancer there are but few points that are really settled. One of these which is apparently beyond question is that old age predisposes to the development of malignant neoplasms. The difficulties in following the cellular changes which lead to tumor formation in man are many and obvious. A precancerous condition is almost impossible of absolute demonstration. A study on animals is also difficult since they often do not develop tumors or else there is little analogy between the growths to be found in animals and in man. Quite recently Goodpasture and Wislocki (*Jour. Med. Research*, 1916, xxxiii, 455) found multiple tumors in very old dogs which were autopsied, and they were led to examine fifteen old dogs which they were able to obtain. As far as could be told from the condition of the teeth, the presence of cataract, and the general appearance, the animals were approximately fifteen years old or older. In all of the fifteen dogs examined they found tumors in several organs, the liver, spleen, and adrenals being most regularly involved. In fact they never failed to find multiple tumors in every dog which they classified as old before autopsy, whereas in hundreds of normal younger animals they never observed a similar condition.

The uniform and coincident occurrence of these tumors, the fact that they were usually multiple in each organ, and a certain similarity in their mode of formation made the authors feel that they were an expression of a common cause, the picture varying with the character of the tissue in which they occurred. The process was followed best in the thyroid. "Here there is first a cessation of function in multiple foci consisting of a few acini. This is indicated by a disintegration of colloid and shrinking of the acini. The epithelial cells become larger by an increase of cytoplasm which is more granular apparently than normal. In some of these acini, before their lumina have completely disappeared and while atypically staining granules of colloid still persist, we find evidence already of beginning proliferation in the increase in number of cells at points along the epithelial linings. Later the former acinus becomes a solid column of epithelium. The atrophic area is thus converted into a small tumor which increases in size both by proliferation of its own cells and by coalescing with other similar areas." Similar changes taking place at the same time in many parts of the body makes it probable that they are due to a common cause and the most probable one is senescence.

The authors did not attempt to classify the tumors, and with one exception found no evidence of metastasis, so that the growths were, at least in this sense, benign. There were histological evi-

dences of rapid growth to be seen in many of the tumors, so that there was always the possibility of rapid extension. Just how this observation will fit into the theory of cancer etiology it is impossible to say; nevertheless the observation seems to be an important one and one that will have to be considered in the evolution of that theory. Obviously it will not fit every instance of malignancy which one meets, and surely it is not the whole cause, but there is the possibility that it may be an important part of the cause.

THE PSYCHOANALYST AND THE PURITAN STRAIN.

IN literature, in art, in manners and morals, there survives in America something of the strait-laced fanaticism of our Puritan forefathers. Diluted it no doubt is by its passage through some eight or nine generations, but nevertheless it is a sufficiently potent force seriously to hamper our artistic life. The criticism consistently levelled at us by our European contemporaries is that we look for the ethical aspect of a work of art, rather than upon its esthetic value. Thus we see upon one hand the condemnation of Theodore Dreiser and September Morn; on the other such things as *Little Elsie* and *Harold Bell Wright*.

It is small wonder then that the psychoanalyst has had a hard road to travel. He has been injudicious enough to confess openly that in tracing back psychoneuroses and certain psychoses through their devious ways he has frequently found himself confronted with sexual difficulties. He has quoted such cases with descriptions of their particular difficulties and in return he has been depicted as a peddler of pornography, a sink of salaciousness, and in general about three shades worse than the mayor of Gomorrah. That this storm of disapproval has at least a considerable part of its source in the Puritan way of looking at things seems fairly reasonable. If this is doubted, a careful review of the various published criticisms of psychoanalysis will show two things: First, an assumption is made that psychoanalysis rests its case upon sex, in the grosser sense of the term, and, second, psychoanalysis is to be condemned forthwith for that reason, not because its logic is faulty or its results unsatisfactory.

A common cry against the psychoanalysts, for instance, is their conception of the sexual life of the child and the various hates and loves he may develop within the home. The stereotyped way of considering the child is that it loves its parents, naturally and inevitably, and yet if one is pressed for a reason the only one which seems to present itself is that a child loves its parents because it is right that it should. It can be shown very readily, however, that the parent represents to the child certain restrictions and limitations against which it chafes. A careful retrospect of one's own childhood will reveal many spasms of rage against the parents, moments when one wished either or both of them dead, not realizing, of course, the full meaning of death. The tendency is to regard these episodes with something akin to superstitious awe, as if they

were the result of temporary possession by an evil spirit, and yet this is, after all, a somewhat ludicrous way to approach a psychological fact, and one which is hardly likely to be of much benefit to coming generations.

We should advise the psychoanalyst then who wishes to promulgate his method to avoid mentioning the intimate method of taking anamneses, not to discuss children at all if he can avoid it, put the soft pedal on sex generally—in short, sugar-coat his pill as much as possible, and perhaps the profession will swallow it.

THE CASUALTIES OF THE SUBMARINE IN PEACE AND WAR.

THE submarine has established its efficiency as a terrible agent of offense in the present war. In order to gain its highest point of effectiveness, it is essential that its officers and crew are especially adapted for the duty that falls to their lot, and, of course, they are carefully selected for this service. In the *Military Surgeon*, January, 1916, Wm. H. Halsey, Past Assistant Surgeon, U. S. N., has an interesting article on the submarine, its casualties in peace and war. He emphasizes the necessity that, as every officer and man is needed for the proper handling of the boat, and the loss of any appreciable number of the crew, say, four or five, might easily place it *hors de combat*, it is absolutely incumbent on the medical officers to see that every one of the crew is physically able and well. The medical officer on duty with submarines must of necessity concern himself much more with the prevention of disease and of accident than with their treatment.

Assuming that the crew are fit physically and mentally, and that the avoidable and remediable dangers from the operation of the boat have all been provided against, there still remain the unavoidable and potential accidents, which are not a few. The various forms in which sickness or death may attack the crew of a submersible boat are enumerated and classified by the author according to the conditions under which the boat is operating.

In addition to these, there are the phobias and psychasthenia as they are exhibited in members of the submarine crew, and therefore a naturally nervous and excitable individual is out of place in a boat of this kind because, once his unstable equilibrium is upset, he may destroy the morale of the crew in an instant.

Among the various ever present dangers of life in a submersible is the danger of gasoline intoxication, the onset of which is insidious, and its violent nervous manifestations make the possibility of its occurrence a cause for much dread. It is obvious that dangers from both within and without menace the life and health of a submarine crew in times of peace, and naturally these dangers, certainly those from without, are greatly intensified in time of war. As Halsey says, "In the last analysis it is upon the courage and resourcefulness, upon the health and well-being of the officers and men that the comparative safety of the submarine must depend."

News of the Week.

Semicentennial of the New York City Health Department.—In 1866, the same year in which the MEDICAL RECORD was founded, the Metropolitan Board of Health was organized to supervise the health of the cities of New York and Brooklyn, the counties of Westchester, Queens, and Richmond, and part of the present county of Nassau. At that time sanitary conditions in this city were inconceivably bad, the death rate being higher than that of any other large city in the world, and apparently increasing. During the fifty years of the Health Board's existence the death rate has been reduced from 36 per 1,000 to less than 14 per 1,000. Among the speakers at the dinner which will be given at the Hotel Plaza on March 9 to celebrate the semicentennial of the establishment of the Health Department, will be Dr. Stephen Smith, who was a member of the original Board of Health in 1866 and is still active in public affairs, being a member of the State Board of Charities.

City Death Rate.—For the week ending February 19, the death rate in New York City was only slightly higher than during the corresponding week of 1915, the figures being 15.20 and 15.03 per 1,000 respectively. The total number of deaths was 1,628 as compared with 1,571 for the same week last year. The difference of 0.17 in the rate, however, is equivalent to only 18 deaths, the remaining 39 deaths being accounted for by the increased population. There was an increase of 7 in the number of deaths due to acute infectious diseases, and 16 fewer deaths due to the acute respiratory diseases. The mortality from influenza, heart disease, and nephritis. The death rate for the first eight weeks of 1916 is 16.14 as compared with 14.81 for the corresponding period of last year.

Chicago Death Rate.—The total number of deaths from all causes in Chicago for the week ending February 19, was 760, giving a death rate of 15.9 per 1,000, as compared with 790 for the preceding week and 820 for the corresponding week of last year, when the rates were 1.5 and 17.5 respectively.

Grip Epidemic in New York.—The New York City Department of Health recently reported, as a result of the bacteriological investigation of fifty cases diagnosed as "grip," that the streptococcus had played the leading rôle in the recent epidemic in the city. In the fifty specimens examined, the streptococcus was found in large numbers in twenty-six, the pneumococcus in nineteen, and the influenza bacillus in nine. The investigations were conducted at the Research Laboratory of the Department, under the direction of Dr. Anna W. Williams, each specimen being examined microscopically and by culture. A somewhat similar investigation conducted some months ago showed influenza bacilli in only one specimen out of twenty examined; since in the present investigation this germ was found in nine out of fifty specimens, it is probable that it also played a part in the recent outbreak.

Health Conference.—A general health conference, participated in by eleven States, the District of Columbia, and Federal and railroad officials, was held early in February at Salt Lake City, Utah. Resolutions were adopted covering methods of procedure for the eradication of rabies epidemic in the Western States; the elimination of Rocky Mountain spotted fever; the use of mangle in inoculation for the eradication of coyotes and wolves, and the adop-

tion of methods for the better care of indigent migratory tuberculous patients. Dr. T. B. Beatty, secretary of the Utah State Board of Health, stated that a disease, not similar to any known or recognized malady, and transmitted, it is believed, by the bite of an infected deer fly, had been noted in two counties in Utah. The disease is severe and in some instances fatal. It occurs in June and July, and about the same time large numbers of jack-rabbits are found dead in the fields. The outward manifestation is an ulceration on the hands, face, or neck, at the site of the bite of the fly believed to be the carrier of the disease.

Medical Prize.—The Argentine Academy of Medicine has offered, in commemoration of the centennial of the independence of the country, a prize of 2,500 pesos for the best unpublished work on a medical subject presented at the Congress of Social Sciences to be held at Tucuman, Argentina, on July 9.

Harrington Lectures.—On May 30 and 31, and June 1, Dr. Milton J. Rosenau of Harvard University of Buffalo Medical School will deliver the Harrington Lectures at the University of Buffalo Medical School. Two lectures will be on anaphylaxis, and the third on "Education for Public Health Service as a Career."

Celli Memorial.—Plans are under way for the erection on the Roman Campagna of a monument in memory of Prof. Angelo Celli, to commemorate his investigations on malaria.

Charitable Bequests.—The New York Association for the Blind has received, by the will of the late Roscoe H. Channing of this city, a bequest of \$25,000, to be known as the Susan Channing Bequest in Aid of the Blind.

By the will of the late Adelena M. Cramer of New York, the New York Hospital receives a bequest of \$5,000, St. Mark's Hospital, New York, \$10,000, subject to a life interest, and the Lutheran Hospital, New York, one-half of the residue of the estate, the value of which is not given.

St. Joseph's Hospital, Yonkers, receives a bequest of \$500 by the will of the late Mrs. Jane E. Cornell of that city.

Death of Centenarian.—Cyril McGee, believed to have been the oldest man in New York State, died at his home in Moira last week at the age of 106 years.

Nurses Graduate.—Six nurses were graduated from the training school of St. Mary's Free Hospital for Children, New York, on February 22.

New Hospital Building.—The contract for the erection of the new building of the Passaic General Hospital, Passaic, N. J., has been awarded, the estimated cost being \$50,800. The new building, which will adjoin the present, one will be 40 x 67 feet, four stories high, of red brick with limestone and terra cotta trimmings, and provided with every modern convenience.

"Mauretania" Withdrawn from Service.—The British Admiralty last week announced that the *Mauretania* was no longer needed by the Government as a hospital ship and is to be withdrawn from service and restored to her owners. The *Mauretania* was used by the Government during the Dardanelles campaign.

Hearing on Mohansic Bills.—A number of physicians and sanitarians appeared at a joint meeting of the Senate Finance Committee and the Assembly Ways and Means Committee to support the bills now before the New York Legislature

which provide for the abandonment of the Mohanic State Hospital and the Yorktown Heights Training School for Boys, and the exclusion of all institutions from the Croton watershed.

Nurses to the Front.—Thirty-three American nurses, many of them from the Mercy Hospital, Chicago, who had been in London for two weeks gathering their equipment, were sent to the front on February 26.

The Harrison Law.—Five prominent physicians of Atlanta, Ga., have addressed to one of the United States Senators from Georgia a letter calling attention to the fact that although nine months have elapsed since Congress passed the Harrison law regulating the sale and use of narcotics, no means have as yet been devised for the proper care of the sufferers addicted to the use of these drugs. While commending the law, these physicians state their belief that the Federal Government should devise some plan to care for these patients, and that a national hospital working in conjunction with the Internal Revenue Department would be more satisfactory than State and County institutions. The State Legislature of Georgia, they say, made a small appropriation for the care of these patients, but the amount was so small that no adequate plan was possible. The note questions whether if Congress had realized the gravity of the new law, provision for the care of drug cases would not have been made in the original act. The letter is signed by Drs. Samuel A. Visanska, Hugh I. Battey, Dunbar Roy, James N. Ellis, and Allen H. Bunce.

The Physicians, Surgeons, and Dentists Fund.—The following appeal has been issued to the physicians and dentists of the United States: "We, the undersigned, having devoted our energies for various lengths of time in helping our colleagues, the surgeons, physicians, and dentists of France; realizing that they are working under terrific stress and strain, under improvised conditions and often with an insufficiency of instruments and material, and feeling that many of our colleagues here would gladly contribute a sum of money monthly for the purchase of instruments and materials here or abroad as wisdom and need indicate; propose that such a brotherly manifestation of solicitude be made, and we call upon our professional brethren throughout this land in sympathy with the cause of liberty and justice, so dear to these two democracies, to pledge themselves to contribute to this fund \$2 per month for the year 1916, from January 1, to be paid monthly or in block. This sum to be placed at the disposition of the American Relief Clearing House in Paris, the official bureau of all American charities, and in constant touch with all necessities over there. These sums to be expended in such a way as they may see fit, advised by a representative of the French Academy of Medicine, and a representative of the Minister of War, in order that the wisest possible use may be made of the funds thus furnished. Further, we solicit donations of instruments in first rate condition, and hospital equipment of all kinds; bearing in mind that in the present crisis everything is needed. May we even ask our colleagues to economize in all wisdom, and not to waste in this land of plenty, but to contribute to the cause that which is saved. Also that they may endeavor to interest their various clients to aid us in our work. We pledge ourselves to our utmost to see that every contribution arrives where there is need for it and feel that this friendly gesture of one country to another through our pro-

fessional channel will be received with a gratitude most touching and bear fruit in the relations between our two countries in the future. What the architects, artists, and sculptors of our country have done for their confrères, who are in the ranks across the ocean, we may well do also." The circular is signed by Drs. George E. Brewer, G. W. Crile, Harvey Cushing, Joseph Flint, Walton Martin, and William H. Potter; and approved by Drs. William M. Polk, John Finney, Thomas P. Hinman, E. C. Kirk, W. S. Thayer, H. Holbrook Curtis, John B. Walker, H. C. Moffit, John A. Hartwell, and Hugh Auchincloss. The chairman of the executive committee is Dr. C. N. B. Camac; the secretaries Drs. Foster Kennedy and William H. Ordway, Jr., and Mr. Whitney Warren. All monies subscribed go to the fund without deduction for administration expenses. Checks should be made payable to J. P. Morgan & Company for the P. S. D. Fund and addressed to P. S. D. Fund, 16 East Forty-seventh Street, New York City. All contributions in material should be sent prepaid to P. S. D. Fund, War Relief Clearing House, 133 Charlton Street, New York City.

Obituary Notes.—Dr. HENRY BAIRD FAVILL of Chicago, professor of clinical medicine in the Rush Medical College and professor of medicine in the Chicago Polyclinic, died in Springfield, Mass., from pneumonia, on February 20, aged 55 years. Dr. Favill was graduated from the University of Wisconsin in 1880 and from the Rush Medical College in 1883, and had practiced in Chicago since 1890. He was a fellow of the American Medical Association, and chairman of the Committee on Health and Public Instruction, a member and former president of the Chicago Medical Society, and a member of the Chicago Pathological Society, the National Society for Mental Hygiene, and the Illinois State Medical Society, and was attending physician to St. Luke's, the Passavant Memorial, and Augustana Hospitals. He had gone to Springfield to deliver an address before the New England Dairymen's Convention on behalf of the National Dairy Council, of which he was president, when he was attacked by the illness which proved fatal.

Dr. JOHN KOPLITZ of Middletown, Conn., a graduate of the University of Munich, Germany, in 1847, died at his home on February 10, aged 94 years.

Dr. RICHARD H. WHITEHEAD, dean of the Medical Department of the University of Virginia, and professor of anatomy, died at his home in Charlottesville, from pneumonia, on February 6, aged 51 years. Dr. Whitehead was graduated from the University of Virginia, Department of Medicine, Charlottesville, in 1887, and was a member of the American Medical Association, the Medical Society of Virginia, the Albemarle County Medical Society, and the American Association of Anatomists.

Dr. ALFRED L. LALIBERTE of Minneapolis, Minn., a graduate of the Laval University Medical Department, Quebec, in 1904, died at his home of pneumonia, on February 5, aged 40 years.

Dr. LEONARD ADAIR of New York, a graduate of New York University Medical College in 1896, died at his home, on February 24, aged 46 years.

Dr. C. M. SCHINDEL of South Omaha, Neb., a graduate of Bellevue Hospital Medical College, New York, in 1887, and a member of the Nebraska State Medical Association and the Omaha-Douglas County Medical Society, died at Spokane, Wash., from apoplexy, on February 11, aged 53 years.

Fifty Years of Medical Progress.

A RETROSPECT of half a century's advance in medicine and surgery—although it opens a vista into many domains not previously accessible to the healing art—yet provides too short an historical perspective for the unravelling of the many tangled skeins of which is woven the fabric of success unparalleled perhaps in any other field of human endeavor. Overshadowed in its second decade by the most destructive of wars, the twentieth century is still too near its threshold to have contributed to a marked extent to the achievements of the latter half of its predecessor.

In a ramble through the wonderland of medical and surgical research from 1866 to 1916, there are many places that invite to rest and meditation on the marvels that have been wrought in the laboratory, by the bedside, on the operating table. The darkness of early medical history is studded, indeed, with stars, few and far between, of the first magnitude; but while such stars are not lacking in our day, the firmament of the modern sciences is sparkling with innumerable lesser lights, and cooperation is the key which has unlocked a thousand intricate problems of disease.

The evolution of the specialist, in the latter part of the nineteenth century, was the natural outcome of the marvellous extension of the so-called seven branches of medicine (anatomy; chemistry, including physics; physiology; materia medica, including therapeutics; practice of medicine; obstetrics; and surgery). New territories were tilled and explored, in the anatomy of the nerves, the eye and ear, the abdominal viscera; the physiology of secretion, including the endocrine glands, and of digestion; autointoxication; psychoneurology, the degenerative diseases, and insanity.

The progress of scientific medicine in the last few decades, and the application of modern knowledge to the therapeutics of internal diseases, are in many instances equally radical though perhaps less striking than the brilliant achievements of modern surgery. Many a priceless pearl has been added to the diadem of medical science by the patient toilers who indefatigably "grope in the abysses of the microscope." New specific remedies for constitutional and other diseases are elaborated every day in the laboratories, and produce results not dreamed of in the medical philosophy of other days. The control of the great epidemics, which only half a century ago swept over entire countries, decimating the population, is one of the most brilliant achievements of modern medicine in its branch of public hygiene, which is largely based on bacteriology, although a series of other factors have also contributed to its evolution. The advance of applied medical knowledge is strikingly illustrated by the discrepancy between the tuberculosis mortality statistics of New York City in 1870 (421 per 100,000 of population) and in 1914 (169 per 100,000).

The last fifty years have more efficiently enlarged the scope of medicine, both as a science and as an art, than had the two preceding millenniums. Modern medicine is characterized by its absolute freedom from philosophical reflexions and its practically exclusive foundation on known facts. The remarkable knowledge of the ancient anatomists, based on the most painstaking and accurate observations, has been vastly extended by the revelations of the scalpel and the microscope. Histology and embry-

ology—now on the curriculum of the freshman and sophomore years of all medical colleges—fifty years ago were studied only by the elect few. Physiology and chemistry, at that time independent fields of investigation, have become allied sciences, and now vie with each other in furnishing the supports on which rests much of present-day medical teaching. Ophthalmology, otology, rhinolaryngology, from modest beginnings in the course of half a century, have become highly important specialties, and are taught in undergraduate as well as graduate schools. The advance of physiology, bacteriology, and hygiene has had a wonderfully stimulating effect on medicine in general. Views on the nature of infectious diseases have undergone radical changes, and their treatment as well as that of constitutional affections has in many instances been practically revolutionized. It is difficult to realize that a practitioner of the old school knew nothing of the fresh-air treatment of tuberculosis, of tuberculin, of serotherapy in general, nor of the ubiquitous Salvarsan medication! He diligently did his work without the aid of our modern improved methods of examination, our excellent instruments, our new apparatus for electro-endoscopic illumination, and so forth. Modern hospital facilities were not missed, because they were barely known. Reflections on endovenous infusion or endocrine medication would have read to the best of the profession, fifty years ago, like the ravings of a madman.

The countless discoveries of the last few decades illustrate the increasing advance of the medical sciences. The surgeon's merciful tools constantly invade hitherto inaccessible cavities and recesses of the human body, for the growth of surgery has been phenomenal, especially so in the domain of vascular surgery. The clinician has learned to re-establish physiological action, and thus to prevent or modify disease, notably with the assistance of serum treatment. If the mystery of disease has been largely destroyed through the detection of its microscopical agents, so has the halo of miraculous power that formerly encircled the brow of the erudite magister of the healing art.

SURGERY.—The teachings of modern surgery have been profoundly modified through the young science of bacteriology, and the introduction of Lister's principles, which revolutionized the older methods of treatment. Lister's first reports on the antiseptic method bear the date of 1867, and the causes of traumatic infections were discovered by Koch in 1878. An equally wide gulf separates modern aseptic work from the so-called "spray and gauze method," which was practised by many of Lister's enthusiastic followers long after the originator had abandoned the carbolic-acid spray. The spirit rather than the letter of Listerian laws was not generally recognized until the late eighties of the nineteenth century. Superseding his corrosive sublimate antiseptics (1877), steam sterilization was introduced into surgery by v. Bergmann, in 1886. Dating from this period, antiseptics was gradually replaced by surgical asepsis, introduced by v. Bergmann in 1891, which is practically equivalent to "germlessness." In connection with this change, the mode of employment of drainage-tubes was likewise radically altered. Improved methods were also devised, such as Michel's clamps and other devices, for the closure of the operation wound.

Esmarch's artificial ischemia, introduced in 1873, to a great extent has given way to Spencer's clip forceps, small nickel-plated clips first introduced by

the English operator, Sir Spencer Wells, which are an indispensable adjunct of the modern surgeon's armamentarium. Besides saving the patient's valuable blood and thereby enhancing the prospects of recovery, the new technique permits a free survey of the field of operation, otherwise apt to be obscured by the hemorrhage. Methods of reducing surgical hemorrhage were perfected in this country and abroad. The application of the Esmarch bandage high up on the body, as proposed by the American operator, R. Dawbarn, serves to withdraw the blood from the arms and the trunk, forcing it downward into the lower limbs, and thereby insuring a minimum loss of blood in operations upon the trunk. Momburg, in Germany, applied the elastic bandage to the waist, thus shutting off the blood supply below that level.

Bier's hyperemia, or passive congestion, introduced in 1903, aims at benefiting diseased tissues by keeping them in prolonged contact with the oxygenated arterial blood, which is thereby permitted to flow freely into the affected part, while the outflow of the venous blood is retarded by the application of an elastic band or other suitable contrivance.

The bearing of surgical anesthesia upon the evolution of modern operations is self-evident. Although general anesthesia dates back to the first half of the nineteenth century, B. W. Richardson introduced the method of local anesthesia by means of an ether spray in 1866; cocaine was first employed as a local analgesic agent in eye surgery by Koller in 1884; and infiltration anesthesia was introduced by Schleich in 1894. Spinal anesthesia and local medication of the cord, often erroneously attributed to Quincke and Bier in Germany, originated in this country, and the new therapeutic procedure was first described by its discoverer, J. Leonard Corning, in 1885. The first paper by Quincke on the technique of lumbar puncture and the study of the cerebrospinal fluid appeared in 1891. G. W. Crile's combination of different drugs (anoci association, meaning exclusion from the operation of all harmful associations), on the basis of his experimental research into surgical shock was reported in an essay awarded the Cartwright Prize for 1897. At the Lakeside Hospital in Cleveland, Ohio, 2,672 operations were performed by Crile up to 1913 with a death-rate of less than 2 per cent.; in the last thousand of these cases the death-rate was less than 1 per cent. (*Divinum est opus sedare dolorem!*—Hippocrates.)

Under the auspices of recent bacteriological, pathological, chemical, and other discoveries, the progress of modern surgery in the last fifty years has been so swift and brilliant as to be best described by the word "phenomenal." Aside from the marvels of technical feats undreamed of in the past, the scientific contributions of contemporaneous surgeons vie with those of pathologists and internal clinicians, in the elucidation of obscure problems of infection, tissue-repair, neoplasms, and so forth. Without entering into detail, advances out of proportion to the small number of decades elapsed since 1866 can be registered in the surgery of the brain and cord; of cancer of the breast; of the stomach and intestinal tract, notably the appendix and the rectum; of the liver and gall-bladder; the pancreas; the thyroid gland; the senile prostate. The scope of major operations on the viscera is constantly increasing, since the first successful cholecystotomy, performed by L. T. Boggs of Indianapolis, in 1867; the first excision of the gall-bladder by Langenbuch,

in 1882, and Kraske's first surgical intervention for cancer of the rectum in 1885.

The introduction of exploratory laparotomy belongs to this period, which also brought the once popular Murphy button. Kussmaul intubated the stomach, in 1867, and twelve years later, in 1879, Billroth performed the first successful excision of the pylorus. Gastroenterostomy was introduced by Woelfler, in 1881.

Modern treatises on abdominal surgery are crammed from cover to cover with new operations and ingenious devices of all kinds, so as to preclude more than a cursory allusion to "the surgeon's playground." A very complete surgical establishment, largely devoted to this branch of surgery, is conducted in Rochester, Minn., by two American brothers, William J. and Charles H. Mayo, perhaps the most widely known of all living surgeons. From all parts of the old world, visitors high up in the profession arrive solely to see the Mayos operate and to study their methods. Cancer of the stomach and intestines has never been more successfully treated than in the Mayo clinics. In England Sir W. Arbuthnot Lane advocates and practises the removal of large portions of the colon, when their stagnating contents become a menace to longevity or to life itself. The "Murphy drip" is an important adjuvant in abdominal operations of all kinds.

Notable advances are to be recorded in the surgery of the chest. The long maintained inaccessibility of the thoracic region—due to the lower air pressure in the lungs than in the outside air—has been overcome by the simple method of intratracheal insufflation devised by S. J. Meltzer of the Rockefeller Institute, which keeps the air in the lungs at the same pressure as the outside atmosphere, so that the chest can be opened without any danger of collapse. Brauer proposed an over-pressure apparatus for the prevention of the dangers and sequelae of pneumothorax. Sauerbruch's pneumatic cabinet, an under-pressure contrivance, was introduced in 1904, and the first sixteen cases operated upon according to this method were reported in 1906.

Intubation of the larynx was first proposed by O'Dwyer, in 1885, who practised it with the tube that bears his name. A few years later, the procedure now in use for the forcible passage of air into the lungs, known as the Fell-O'Dwyer method, was first described by its originator. Direct laryngoscopy was introduced by Kirstein in 1894, and direct bronchoscopy by Killian in 1898. Matas, in 1902, described artificial respiration by direct intralaryngeal intubation with a modified O'Dwyer tube, and a new graduated air pump, in its applications to medical and surgical practice.

The surgical treatment of renal disease has been enriched by new operative procedures, such as anchorage of floating kidney; radiographic recognition and extraction of calculi; drainage of renal abscess; nephrectomy; interventions upon the ureters. The extirpation of a diseased kidney was first devised and performed by Simon, in 1869. (Walcott of Milwaukee had removed a kidney in 1861 in the extirpation of a supposed cystic tumor of the liver pressing on the kidney.) Hahn, in 1881, carried out the first nephropexy. The introduction of the cystoscope by Nitze, in 1899, marked a new era in the surgery of the bladder. The technique of vesical operations was greatly improved through the elevation of the pelvis, according to Trendelenburg.

Goiter-surgery has reached a high state of development, through the work of Kocher, Mayo, Payr, and other prominent operators, in this country as well as abroad. The medical treatment of exophthalmic goiter and other affections of the thyroid gland has failed to show results even approaching those realized by the hand of the surgeon.

Hitherto neglected structures, such as tonsils, adenoids, post-nasal vegetations, have acquired surgical importance. The first operation on adenoids dates back to 1868, when Meyer performed it, in Copenhagen, Denmark. A number of improved methods for harelip and cleft palate operations, and others too numerous to mention, must be credited to the plastic surgery of the last half century. Paraffine injections were first employed by Gersuny, in 1900.

Orthopedic surgery, practically an American creation, has never flourished as it does at the present day. The modern transplantation methods of bones and joints (Koenig, Lexer, Albee) represent a wonderful extension of the early methods of skin-transplantation (Thiersch) which opened up a new field of experimental research, especially after Davis of Johns Hopkins University had demonstrated the practical applicability of transplanting large flaps of skin.

Plaster of Paris bandages were first introduced by a Belgian army surgeon, Mathysen, who died in 1878, but were improved and popularized by another Belgian, Hubert van de Loo, who survived him five years. Sayre's gypsum corset for spinal deformities was introduced in 1876.

Vascular Surgery.—The advances in the field of vascular surgery are marked especially by the enormous progress and extraordinary development of the suture, as applied to the bloodvessels, since 1881, illustrated by Murphy's successful circular anastomosis of bloodvessels, in 1896; and culminating in Carrel's methods of vascular anastomosis and tissue transplantation, in 1902.

With the introduction of cardiorrhaphy, the heart itself ceased to be a surgical *noli me tangere*, until now it has not only become a surgical organ, but represents one of the most gratifying fields for the display of operative ingenuity. "The road to the heart is only two or three inches in length in a direct line, but it has taken surgery nearly 2,400 years to travel it." (Harry Sherman.) The knowledge obtainable up to 1868 is embodied in the monograph of George Fischer and dating from that time it was greatly extended by the experimental work of Italian and German investigators. The surgical period begins with Farina's first case of heart-suture, in 1896, and successful cardiorrhaphies are now reported in considerable number, after injuries of all parts of the heart. Separate injury of the pericardium, contrary to former belief, is now known to occur with relative frequency, although wounds of the pericardium rarely remain uncomplicated. At the present advanced state of cardiovascular technique, the outcome of these cases depends largely upon the associated and subsequent complications.

The extraction of a thrombus from the pulmonary artery, after the vessel has been exposed and incised—first performed by Trendelenburg, in Leipsic, Germany—is a most intrepid and often successful emergency procedure, also applicable to the removal of thrombi from bloodvessels in general. Other important advances are represented by the transplantation of segments of arteries and veins; the

insertion of venous segments between the cut and separated ends of a divided artery; the utilization of venous segments for the patching of bloodvessels, ureters, and other tubular structures; the substitution of the venous for the arterial system, when this is obstructed, as a carrier of oxygenated blood (Wieting's operation for reversal of the blood current), and a number of minor manipulations, such as utilization of veins for the drainage of lymph.

Endoaneurysmorrhaphy, the Matas method of intrasaccular suture as applied to the cure of aneurysm, must be accorded a place by itself. This procedure—a triumph of American surgery, with results unequalled by any other method—was introduced over a quarter of a century ago by the pioneer and leader in the domain of vascular surgery. Its excellent results are best shown by Matas' analysis of 225 cases treated according to the method of intrasaccular suture by different operators, with only nineteen deaths (8.4 per cent.), an unequalled record, especially as from this total gross mortality, nine cases must be deducted as not attributable to the operation but due to inevitable accidental or associate conditions. (XVII International Congress of Medicine, London, 1913.)

One of the real advances in the surgery of the vascular system during the last few years consists in the preliminary testing of the collateral circulation, before attempting any operation upon the arteries. The insistence with which attention has been called by Matas to the preliminary testing of the circulation, prior to any interference with accessible arterial bloodvessels, as a means of determining the indications and prognosis of the operation, is regarded by the eminent teacher as one of the most useful of his exhortations. Surgical obliteration of the great vascular trunks was formerly inseparable from the operative treatment of aneurysm. The Matas method of immediate and total occlusion of the artery, by means of simple flexible aluminum bands, as a preliminary test of the efficiency of the collateral circulation, is typical of the conservative trend of modern surgery. The advantages cannot be over-emphasized of a preoperative knowledge of the possibilities of the collateral circulation, meaning the behavior of the peripheral circulation in the dependent regions and organs after the occlusion of the main surgical arteries.

The aseptic absorbable ligature, evolved on the basis of Listerian principles and now produced under practically ideal conditions, has been the means to the twofold end of surgical progress in general, and of the improved aseptic vascular suture in particular.

The treatment of hemorrhage, surgical and constitutional, has been enriched by new methods, notably by improved direct transfusion and serotherapy. Before performing direct transfusion, the modern surgeon ascertains that the serum of the donor does not agglutinate the erythrocytes of the recipient, or vice versa, by means of a careful examination of the serum and blood of both parties concerned in the exchange. In regard to serotherapy, Matas writes that "this mode of treatment, while not at all specific in its character, is based on a rational principle, and has yielded sufficiently encouraging results since its introduction, to deserve further trial, not only in hemophilia, but in all the allied hemorrhagic states."

Modern *brain surgery* successfully attacks many regions, notably the base of the brain, formerly considered as inaccessible in the living. Tumors of the

hypophysis, for example, are now unhesitatingly removed by expert surgeons (Harvey Cushing; Hirsch). Interference with the Gasserian ganglion in severe trigeminal neuralgias, was originally the idea of an American surgeon, J. Ewing Mears, who first gave this advice in a lecture held before the American Surgical Association, in Philadelphia, in 1894. The radical operation was first performed by Rose, in London, in 1890, and since that time has been greatly improved and modified. The approved technique of radical extirpation was established by Hartley in America and Krause in Germany.

Remarkable advances have been made in the surgery of the spinal cord, since the operations of Gowers and Horsley, in 1889; such as Förster's operation for locomotor ataxia, by means of resection of posterior roots, proposed in 1909. Intramedullary affections of the spinal cord were rendered accessible through improved methods of laminectomy, notably the work of Elsberg (1912). Surgical diseases and injuries of the nerves have been vastly benefited by the improved modern methods of nerve-resection and nerve-suture.

Surgical Gynecology.—It has been aptly said that surgical gynecology, as represented by the two major operations of ovariectomy and hysterectomy, is typically American. The first vaginal ovariectomy was performed, with a successful outcome, by T. Gaillard Thomas, in 1870; Robert Battey, of Atlanta, removed the ovaries for the production of an artificial menopause, in 1872; T. A. Emmett, in 1874, advocated and performed the repair of a lacerated cervix. Vaginal hysterectomy of the cancerous uterus was first performed by Mary Amanda Dixon Jones, in 1887, according to her original procedure by which the operation was considerably shortened (15 minutes); the patient recovered and was free from recurrence six years later.

In discussing the evolution in America of abdominal hysterectomy and total extirpation of the uterus, Cushing, in 1895, enumerated the following contributions to surgical gynecology in the last half century: Cutter, first application of galvanism to uterine myomata, 1874. Trenholme, first application to treatment of uterine myomata of Battey's operation of ablation of appendages, 1876. Valuable modifications of the intraperitoneal method of treatment of the stump, Marcý, 1881. A series of improvements in the technique of the extraperitoneal method of treating the stump by which intraligamentous tumors and those deep in the pelvis can be removed, J. Price and his pupils, 1886. Total abdominal extirpation of myomatus uterus, by use of clamps (first resuscitation in America of the operation since those of Freund had been abandoned), Lewis, 1888. First separate ligation of the uterine arteries in their continuity and total extirpation by this method, Stimson, 1889. Method of total extirpation by use of a staff, Eastman, 1889. Total abdominal extirpation, fastening stump of vagina to abdominal incision, for prolapse, Polk, 1889. Methods for making the stump intraabdominal but extraperitoneal, Polk, 1888, Kelly, 1890, Byford, 1890, Baer, 1892. Total abdominal extirpation of the uterus with suppurating appendages, as a matter of election, Baldy, Polk, 1893. Enucleation of the stump as well as the myoma, by the use of a serrated gouge, without severing the uterine arteries, Eastman, 1894. Total extirpation of uterus, in cases of extrauterine pregnancy, where the tube which is not pregnant is diseased, Krug, 1894.

Important events in the history of surgical gynecology during the last five decades are represented by Porro's cesarean section, with excision of adnexa, in 1876; Freund's extirpation of the cancerous uterus, in 1878; Czerny's vaginal excision of uterine tumors, 1881; Saenger's improved cesarean section, 1882; Lawson Tait's operation for extrauterine pregnancy, in 1883; Howard Kelly's hysterorrhaphy, 1887; Wertheim's radical operation for cancer of the uterus, in 1900. The trend of modern gynecology is essentially conservative, and the once fashionable massacre of innocent ovaries (supposedly superfluous adnexa) is now unconditionally rejected.

OBSTETRICS.—The most important advance in the science and art of obstetrics is probably represented by Duehrssen's method of vaginal cesarean section (1896), and the extension of the indications for cesarean section in general. A number of new methods have of late been devised for transperitoneal and extraperitoneal cesarean section. Obstetrical analgesia through a combination of drugs (twilight sleep) is a very recent and as yet incompletely tested innovation. The newer obstetrical teachings were given a changed direction by the discovery of latent gonorrhea in the female (Noeggerath, 1872) and the introduction of Credé's silver-nitrate instillation for infantile conjunctivitis.

Abderhalden's announcement of the ferment-reaction, in the diagnosis of pregnancy, in 1913, is a very recent addition to obstetrical science and opens up a wide vista into as yet imperfectly explored territory. Blood serum derived from a pregnant woman can by these means be distinguished from the serum of a woman in whom pregnancy does not exist and childbirth has not recently occurred. By the majority of writers, this pregnancy reaction is considered as an eminently useful method, provided the tests can be carried out in a reliable manner, in scientific laboratories, like other serological reactions.

PATHOLOGY.—From this lusty branch, sprung from the tree of medical science in the nineteenth century, the physician has been enabled to gather many golden fruits of practical utility. He has become familiar with the normal characters and conditions of healthy tissue, as well as with abnormal conditions, functional irregularities, and disorders of metabolism, through the important advances of the last few decades in all realms of pathological research. Many diseases were for the first time submitted to pathologico-anatomical investigation, and their pathogenesis and etiology no less than the pathological anatomy itself thus came to be better understood. The teachings of inflammation underwent important modifications. Malignant tumors received special attention, more particularly in regard to histogenesis and metastases. The cancer problem gave rise to extensive experimental research and indirectly to many useful discoveries, such as Coley's fluid for treatment of sarcoma. Anomalies of growth were carefully investigated, and conditions such as cretinism, tetany, acromegaly, gigantism, fetal chondrodystrophia, were traced to their source, in disturbances of the internal secretions. The so-called lymphatic constitution was definitely referred to persistence of the thymus. (Waldeyer, 1890.) The goiter question led to important experimental and other work upon the thyroid gland. Conditions pertaining to the vascular system, and circulatory disturbances, came to be better understood on the basis of the modern teachings of thrombosis and organization of the throm-

bus. Important contributions appeared on the subject of retrogressive nutritional disturbances; local tissue necrosis and gangrene; deposits of urates; pathological pigmentations; regeneration of muscle and nerve tissue; compensatory hypertrophy, and so forth. Hematology was enriched by the detailed study of the erythrocytes and leucocytes, progressive pernicious anemia, hemophilia, myelogenous leukemia, and inflammatory leucocytosis.

Many important contributions were added to the pathology of the brain and cord, notably tumors, as well as to the subject of neuritis, and nerve-repair. Idiopathic muscular atrophy and pseudomuscular hypertrophy attracted the attention of investigators. Neighboring lesions of mucous membranes (specific infection of the rhinopharynx) have recently been pointed out as the shortest road of the *Spirochaeta pallida* to the brain, resulting in cerebral syphilis, so resistant to medication. (W. Sohler Bryant.) The pathological histology of all eye diseases became a fruitful field of research; important additions were made to the knowledge of keratitis, glioma and neuroepithelioma of the retina. A better knowledge of errors of refraction in the eye has only recently come to be the common property of medical practitioners. The etiology and genesis of acute otitis media were established by German investigators. A number of learned contributions appeared on the pathological histology of the labyrinth. (Bárány; v. Cyon.)

The pathology of the respiratory and related systems was enriched by the investigations of nasal diseases, accessory sinus disease, pulmonary emphysema, pneumoconiosis. Kocher studied the problem of cachexia strumipriva, and the histopathology of goiter was discussed in many important contributions to the literature. Gull described myxedema in 1873. The parathyroid glands were described by Sandstroem in 1880. Important clinical and experimental contributions to the physiology of the thyroid and the parathyroids were published by Pineles in 1904. Acromegaly as connected with the hypophysis was discussed by Marie in 1886, and Cushing, in 1911, described dyspituitarism. The first case of tumor of the carotid gland was reported by Marchand, in 1891.

The digestive system was not neglected, and valuable articles appeared on tuberculosis of the salivary glands; on esophageal diverticula; peptic ulceration of the esophagus; muscular pyloric stenosis; gastric ulcer and cancer; uremic necrosis of the intestine (Treitz); and intestinal catarrh (Nothnagel). Fifty years ago "inflammation of the bowels" was a much used elastic term, which covered a multitude of sins, now tracked and labeled as colitis, enteritis, pelvic cellulitis, peritonitis, and, last but not least, appendicitis. The indications for early laparotomy in appendicitis, and the now famous McBurney's point were first emphasized in 1891. Articles, long and short, pamphlets, monographs, entire books, were published on the pathology of the vermiform appendix. Numerous contributions of pathological interest concerned the liver (cirrhosis and infarction) and the pancreas (fat necrosis and tuberculosis).

In regard to the uropoietic system, the last half century brought important investigations on the subject of Bright's disease, on the origin of cylinders in the urine; on hypernephroma of the kidney (Grawitz), urinary calculus, and other diseases. The suprarenals were recognized as having an important bearing on metabolism.

The regenerative rôle of bone-marrow in hemorrhage came to be properly understood. Osteomalacia and rachitis became the subject of careful investigation. Coxa vara was studied by v. Bruns, and scoliosis by Albert and Nicoladoni. Anomalies of the bony pelvis were described, in general as well as in particular, and the neuropathic arthritides attracted the attention of pathologists.

PHYSIOLOGY.—Modern physiology is closely linked with pathology, if not inseparable from its problems. The scope of physiological chemistry is far-reaching and embraces the many variegated chemical processes going on in the animal body, such as muscular contraction (a largely chemical phenomenon); metabolism in the liver; the formation of the digestive enzymes; the physiological and pathological part played by the internal secretions. Through its revelations on the subject of chemical bacterial toxins, produced by the activity of microorganisms, the physiological chemistry of the present day is likewise closely linked to bacteriology. The chemical activation of the sea-urchin's egg by Jacques Loeb startled the scientific world in 1899.

The study of the ductless glands—in the foreground of professional interest at the present writing—was inaugurated by the establishment of the fact of internal secretions, by Brown-Séquard, in 1891; followed by the work of Sajous, in 1903.

The action of the digestive glands was investigated by Pavloff, in 1898. The study of metabolism, led by v. Noorden, began in the years 1892-95.

Nearly fifty years ago, in 1870, the localization of function in the cerebrum was established by Fritsch and Hitzig, followed about twenty years later by Monakow. Bowditch demonstrated the non-fatigability of nerve-tissue in 1890. The phenomena of neuromuscular fatigue and exhaustion and the study of the so-called fatigue-toxins have recently attracted the attention of investigators, especially in this country and in Germany (Weichardt). A better knowledge of the structure of the nervous system was inaugurated by Golgi's staining method, discovered in 1873, but not practically applied until the publication of his work ten years later. The now generally accepted neuron theory (Waldeyer, 1891) rests upon the histological investigations of Golgi, Ramon y Cajal, van Gehuchten, and others.

About half a century ago the work of Charcot, on hysteria, attracted as much attention as the evolution of psychoanalysis (Freud) in the present generation.

The internal unity between nervous physiology and nervous psychology was emphasized by Forel, and a wider vista into the delicate and complicated relations between the genic instinct (libido) and nervous disease was opened up by the work of the Vienna neurologist, Freud, who explains psychoneurotic disease as the result of a mass of suppressed sex-desires. The symptoms are attributed to the fight of the desire against the suppression, and the diagnosis is based upon the detection of the underlying genic factor, by means of the modern method of psychoanalysis. The treatment aims at changing the patient's attitude toward his complexes, or, more simply expressed, restoring his emotional balance.

DIAGNOSIS.—Important diagnostic procedures, unknown fifty years ago, are represented by the Widal reaction in typhoid fever, a practical application of the agglutination-phenomenon; the serum-diagnosis of tuberculosis, syphilis, and other constitu-

tional diseases; the modern diagnosis of rabies by the Negri bodies; cytodagnosis, based upon microscopical demonstration of cell-contents in various body-fluids; cryoscopy, or the determination of the constitution of urine by the establishment of its freezing-point; a great variety of methods for the early recognition of gastric cancer, and a number of other diagnostic adjuvants.

BACTERIOLOGY.—The seventies of the last century brought Pasteur's immortal work on the pathogenic microbes, and his protective inoculations against infectious diseases (chicken-cholera, malignant edema, and hog-erysipelas). In the eighties, his famous protective inoculations against anthrax and rabies (lyssa) were first introduced. The great representative of French medicine was honored, in recognition of his merits, by the establishment of the Pasteur Institute in Paris, with its splendidly equipped laboratories for scientific research.

The discovery of the resistant anthrax spores belongs to R. Koch, in 1876, and started a new bacteriological era, especially in Germany. The first volume of the *Mitteilungen aus dem Kaiserlichen Gesundheitsamt* was published in 1881, and contains a description of Koch's new methods for the isolation and pure culture of bacteria, on which are based the laboratory methods now in general use.

Improved staining methods and dried blood smears were introduced by Ehrlich, in 1874, after Weigert's bacterial stain with carmin, announced in 1871, had considerably advanced the older laboratory technique.

Many germs the names of which are now familiar even to the laity first became known in the course of the last few decades; such as the streptococcus and staphylococcus; the diplococcus of pneumonia; the meningococcus intracellularis; the colon bacillus; the bacillus of rhinoscleroma; the bacillus of leprosy; the bacillus of influenza.

The spirillum of relapsing fever was described by Obermeier, in 1873, and the parasitic ameba in dysentery, by Loesch, in 1875. Anthrax bacilli were first grown on artificial media by Koch, in 1876. Pasteur, one year later, described the bacillus of malignant edema; and Neisser, in 1879, discovered the gonococcus. The streptococcus and staphylococcus were for the first time isolated by Pasteur, in 1880. In the same year, Eberth succeeded in isolating the typhoid bacillus. The ameba of malarial fever was discovered in 1881, by Laveran, who received the Nobel prize in 1907 for efficiency in contagious and epidemic diseases. The epidemic nature of poliomyelitis was discovered by Medin, in 1881. Koch's discovery of the tubercle bacillus was announced in 1882 and in the same year, Löffler discovered the bacillus of glanders, followed, in 1883, by Klebs' discovery of the diphtheria bacillus; and in 1884, by Nicolaier's discovery of the tetanus bacillus. The colon bacillus was discovered by Escherich, in 1886. Weichselbaum discovered the meningococcus, and Bruce the bacillus of Malta fever in 1887. The paracolon and paratyphoid bacilli were described by Gilbert, in 1893. In the same year, Smith and Kilborne reported the transmission of Texas fever by the cattle tick.

Blastomycosis was first described by Gilchrist of Johns Hopkins University in 1893. Kitasato and Yersin, in 1894, discovered the bacillus of bubonic plague.

The discovery of bacteriolysis, by Pfeiffer, in 1895, and of bacterial agglutination by Gruber, in 1896, as well as the Widal-Sicard agglutination test

for typhoid fever, are the notable contributions of the year 1896 to bacteriology. The next year brought Shiga's discovery of the dysentery bacillus; and Bordet's discovery of bacterial hemolysis. Filterable viruses were now investigated by Löffler and Frank. Loos demonstrated the transmission of hookworm infection; Smith differentiated between human and bovine tubercle germs (1898). Finlay's theory of the transmission of yellow fever by mosquitos was conclusively proven by the U. S. Army Commission in 1899. Four years later Dutton and Ford discovered the parasite of sleeping sickness, and Bruce, in 1903, showed the transmission of the disease by the tsetse fly. Koch conducted his investigation of African fever in 1908. In the same year the bacillus of pertussis was discovered by Bordet and Gengou.

Modern contributions more or less directly related to bacteriology are represented by Wassermann's serodiagnosis of syphilis, with the Noguchi modification of this test; v. Pirquet's cutaneous reaction in tuberculosis; Calmette's and Wolff-Eisner's conjunctival reaction (1907); Flexner's experimental production of poliomyelitis (1910). Peyton Ross, in 1911, successfully transmitted sarcoma with filterable virus. Very recently, the plasmodium of malaria has been cultivated in the test tube by Bass (1912). Malaria in Italy was combated by Celli and his fellow workers.

The attention devoted to phytoparasitology is constantly on the increase. Much important work has already been done along these lines and the last half century has firmly established the pathogenesis of many infectious diseases, such as tuberculosis, actinomycosis, leprosy, typhoid fever, gonorrhea, a variety of forms of cerebrospinal meningitis, pneumonia, endocarditis, tetanus, and others.

Organized preventive medicine, based on bacteriological and kindred discoveries, first took root in the early years of the twentieth century. The Eastern countries, Africa, and certain parts of the United States became the theater for the display of dauntless perseverance and wonderful success, in the study of tropical medicine. Sleeping sickness, beriberi, tropical dysentery, and other dangerous diseases of warm climates are now under reasonable control. Yellow fever was checked as a result of the work of Reed, Carroll, Lazear, and Agramonte, confirming Finlay's belief that the infection is carried by a certain species of mosquito. Havana, formerly a hotbed of yellow fever, could now be freed from the ravages of the disease within three months, by Gorgas, whose unrivalled feats in sanitation later on permitted the construction of the Panama Canal. In consideration of his research work into the causes of sleeping sickness and Malta fever, the Dutch Academy has just conferred the Leeuwenhoek Medal on the British scientist, Sir David Bruce. His predecessors in this distinctive award, which is bestowed every ten years, were Ehrenberg (1875), Ferdinand Cohn (1885), Pasteur (1895), and Beyerinck (1905).

A new system of combating bacterial infection by means of vaccine therapy has been based upon recently acquired knowledge of the defensive properties of the blood, and the teachings of immunology. (Metchnikoff, Wright, and others.)

The American army surgeon Ashford successfully controlled hookworm disease in Porto Rico, in 1903-4; and Stiles, in the southern United States, in 1910-12. Loos (1910) showed that the hookworm larvæ penetrate the skin.

THERAPEUTICS.—The therapy of disease has been greatly advanced through valuable chemical discoveries, premeditated rather than accidental. To industrial chemistry the physician is indebted for the inexhaustible offerings of the modern pharmacopeia. Whereas prior to the year 1869, practical medicine labored under a deficiency of medicinal agents, the market is now literally flooded by an excessive supply of preparations of all descriptions, and the conscientious practitioner is confronted with the stupendous task of ascertaining the actual advantages of the individual remedies. Indirectly through the achievements of experimental pharmacology, the general practitioner has learned to gauge more accurately the effect and scope of his prescriptions. The old "shotgun prescription" is a thing of the past, and in its place we have simple, purposeful remedies, carefully planned and dosed so as to meet the requirements of a given case. The days are gone, never to return, when it could be said, even in jest, of a brother practitioner: "His pills as thick as hand grenades flew, and where they fell, as certainly they slew." (Roscommon.)

Selecting some salient milestones on the road from half a century ago to now, we find the first marking the discovery and demonstration of the hypnotic properties of chloral hydrate by C. Liebreich, in 1869. Salicylic acid, with its antiseptic effects, was isolated by Kolbe, in 1874. About this time pilocarpine was first recommended as a remedial agent. Trypsin was discovered by W. Kühne. Iodine was introduced into surgery by Mosetig Moorhof in 1880. The hemostatic effect of the fluid extract of *hydrastis canadensis* was demonstrated in 1883. The introduction of ichthyol into medical practice, by Unna, dates back to the same year. Antipyrin was first prepared in 1884, by Knorr, the year in which cocaine was introduced as an anesthetic in eye surgery. Antifebrin and acetanilid were prepared by Cahn and Heppe, and sulphonal by Baumann, in 1886. Salol was introduced in the same year by Marcel von Nencki. About this time strophanthus was recommended as a substitute for digitalis, by T. Richard Fraser, in Edinburgh. Creosote gained in popularity as a remedy for tuberculosis, and was followed by guaiacol. A very important and beneficial contribution of industrial chemistry to medicine is represented by Behring's antidiphtheritic serum, introduced in 1893. Four years later, in 1897, E. Fischer synthesized caffeine, theobromine, xanthin, guanin, and adenin. Dreser, in 1898, introduced heroin. The discovery of erespin by Cohnheim was reported in 1901. Veronal was introduced by Fisher and v. Mehring, in 1903. Einhorn, in 1905, discovered novocain. The announcement of Ehrlich's side-chain-theory, and his introduction of salvarsan, in 1909, bring the recent achievements of medical chemistry practically up to date.

Rather than the securing of the very latest dates and terms, the object of this review is to show the direction of the road that for fifty years has been creditably traveled by members of the medical profession less well equipped than we are with therapeutic facilities. A host of pharmaceutical and biological products for the prevention or cure of disease, constantly superseding one another, are flung annually, not to say monthly, at the bewildered clinician. Numerous synthetic agents have been created, and relatively recent preparations have become more or less indispensable. From the old tried and tested remedies, the efficient substances

are now separated in pure, reliable, and convenient form. The modern application of standardizing by medical and physiological methods the materia medica products, has resulted in an admirable uniformity and reliability of such offerings as compared to those available half a century ago, before the general introduction of standardization methods.

The growth of the pharmacal and pharminochemical industries has been so rapid and exuberant that the great manufacturing houses engaged therein now conduct scientific departments and well-equipped laboratories, under the direction of specialists and experts. Endeavors, not universally sanctioned, are being made to effect a cooperation between university laboratories devoted to purely scientific research and those of manufacturing houses, under the claim of promoting information on therapeutic subjects.

The introduction of clinical laboratories, now indispensable for bacteriological and kindred research, belongs to the second half of the nineteenth century. The first of its kind was probably the clinical laboratory of Ziemssen, in Munich, founded in 1885. Johns Hopkins University not long afterward provided for a similar establishment.

Three distinctive modern weapons in the fight against disease are serotherapy, organotherapy, and chemotherapy as exemplified by the new salvarsan-therapy of syphilis, inaugurated by the investigations of Paul Ehrlich.

Serotherapy is either curative, when it consists in the utilization of blood serum for the cure of an attack of infectious disease; or protective, when it is employed for the prevention of disease. A number of contagious diseases do not attack the body more than once, but leave it in a state of temporary or permanent immunity. The conditions governing immunity have only recently been elucidated by the work of Ehrlich, Behring, and other investigators who have shown that under the influence of the infectious disease, the body is enabled to produce substances which counteract the infectious material. This action may be twofold, namely bactericidal, by attacking the bacterial agents directly; and antitoxic, by destroying the poisonous bacterial products (toxins and toxalbumins). If the bactericidal and antitoxic action overcome the infectious products, recovery results, and moreover certain body elements have acquired the capacity of permanently forming the protective substances (alexins), so that in case of a new exposure to it, the disease fails to develop. This acquired property of the body to protect itself through its own protective substances against renewed attacks of the same disease, is known as active immunity. The protective substances are contained in the blood, and are stimulated to increased production whenever infectious material again enters the body; so that the amount of protective substances in the blood of actively immune animals is greatest soon after accidental or artificial infections. The blood serum of such immune animals, when incorporated into other animals, may exert a double effect: It acts as a curative serum in diseased animals, where its bactericidal or antitoxic substances attack and destroy the pathogenic products. In the blood of healthy animals which are treated with immune serum, the newly incorporated antitoxins are also preserved for some time, rendering the animal passively immune against the disease during that period. This form of immunity, which is always of short duration, is known as passive immunity, because the immuniz-

ing substances are not produced by the body itself, but are introduced from without. Inoculation of such passively immunized animals with highly toxic infectious material invests them with the capacity of producing their own protective substances and thus acquiring an active immunity of fairly long duration. The commercial preparation of antidiphtheritic serum is based upon these principles. It is interesting to note that the discovery of the bactericidal powers of blood serum, now so widely known and exploited, dates back to Nuttall, in 1888. In the same year the toxins of diphtheria were for the first time investigated by Roux and Yersin. One year later, in 1889, Buchner discovered the alexins (protective bodies) and Behring, the antitoxins, with which he later treated diphtheria in 1890. This was also the year of the introduction of tuberculin, by Koch.

Organotherapy and Endocrine Medication.—The recently adopted plan of treating certain evidences of disease by means of routine administration of glandular organs of internal secretion, is also known as endocrine medication. It was ushered in by Kocher's experimental feeding of goiter-patients, whose thyroid gland had been extensively removed, with raw thyroids of sheep and calves. The early investigations of Brown-Séquard are also of importance in this connection. The internal use of ovarian substances from animals, mostly cows, was promptly suggested in gynecological circles, for women whose ovaries had been extirpated on account of disease. The administration of animal suprarenals was found to retard the course of Addison's disease. Adrenalin, the active principle of these organs, was isolated by Takamine, in 1901. Recently, the use of spleen and bone-marrow has been recommended in chlorosis, kidney in nephritis, pancreas in digestive disturbances, hypophysis in certain nervous diseases and acromegaly, etc., etc. Although it is not easy to exclude the element of suggestion in a number of the cases, organotherapy seems to rest on solidly established facts. The new knowledge of the action of the thyroid on cretinism and goiter, as well as certain forms of obesity and skin-disease, constitutes a well-grounded and permanent gain in the therapy of disease. At the same time, the new method of treatment has the merit of emphasizing the dignity and significance of all the organs and tissues of the body.

Salvarsan (neosalvarsan) is the trade name of the Ehrlich-Hata arsenic preparation 606, and its modification, which has recently supplemented the mercury and iodide treatment of syphilis. Ehrlich's work on the experimental chemotherapy of the spirilloses, notably syphilis, was published in 1910. Through Schaudinn's discovery of the *Spirochæta pallida* in 1905, and the demonstration of latent syphilis, modern medicine has been enabled to achieve one of its greatest triumphs as a healing art. The serodiagnosis of syphilis was introduced by Wassermann, in 1906. Noguchi's modified test followed soon, and the luetin reaction a little later. The demonstration of spirochetes in the tissue of the nervous system, by Noguchi, in 1913, has elucidated some hitherto unsolved problems as to the part played by syphilis in certain fields of neurology. The diagnosis and treatment of syphilis and the so-called parasymphilitic diseases have thus been placed upon a new basis.

Heliotherapy dates back slightly over fifty years, but was first placed on a scientific basis by Fin-

sen's investigations in 1893. The Finsen light, the quartz lamp, actinic ultra-violet rays, are now employed in the treatment of skin diseases, as well as some rheumatic and neuralgic conditions. The future of light-treatment would seem to be more promising than that of electrotherapy, which has hardly come up to expectations.

Radiotherapy.—In December, 1895, Roentgen, in Würzburg, discovered the rays which bear his name and gave them the temporary name of *x*-rays, under which they are commonly known. Two years later, a special institute for *x*-ray examination was founded in Berlin. The most immediate benefits of this discovery were naturally reaped by the operating surgeon, as the *x*-ray permits the localization of opaque substances imbedded in soft tissue and a decision as to the prospects of operative interference for the removal of foreign bodies or the adjustment of fractured bones. Anatomy and morphology have also found a useful adjunct in the *x*-ray. At the present time, the Roentgen rays are in use not only for diagnostic purposes, but also as a therapeutic measure, especially in dermatological practice. Clinicians are still divided as to their value in the treatment of cancer and other tumors, malignant and non-malignant. Internal medicine profits through the representation by the *x*-ray of the deeply situated structures of the body, and the observation of the vital processes of organs, by means of the fluorescent screen.

There is still among surgeons a certain degree of skepticism as to the part radium is destined to play in surgical therapeutics. If time brings a moderation in its now almost prohibitive cost, radium may be destined to become a useful adjunct in the treatment of superficial malignant growths, of rodent ulcers, and certain cases of angioma and vascular nevus. Deeply seated cancerous growths, when beyond the reach of the surgeon's knife, will, however, it is to be feared, prove inaccessible to this newly discovered remedial agent. It is possibly destined to play a still more important rôle as a therapeutic agent in internal medicine, in the treatment of neuritis, arteriosclerosis, arthritis, and various other maladies; but here also it is still in the trial stage and it is too early to affirm or deny its curative powers in these affections. Special institutes have been founded in London, New York, and other cities for the investigation of the physical and therapeutic properties of radium.

The keynote of modern therapeutics is the treating of the patient rather than the disease. Although medicinal and surgical measures are invaluable in so far as life is preserved and health restored, the general management of diseased conditions has a similar importance. Not only is the patient protected against further injury, by modern hygiene and dietetic régimes, but his general constitution is improved. Modern physico-dietetic methods aim at preserving the individual's vitality, rather than at specific treatment of local disturbances. It is only very recently that the true relevance of constitutional and hygienic factors has come to be properly recognized. A forerunner of modern methods of treatment is represented by the "rest-cure," inaugurated by S. Weir Mitchell, in 1877.

The cooperation of modern medicine and prophylactic social hygiene in the last few decades, has brought about an extension of the average duration of human life. While the infant mortality has been

the most strikingly benefited—largely through the milk-crusades in defense of bottle-babies—the general mortality figure has also been more or less reduced in all large cities which have introduced radical hygienic improvements. Hygienic successes rest upon compulsory vaccination, disinfection, and fumigation, tuberculosis sanatoria, proper canalization and sewerage, pure water and milk supply, hospital facilities, industrial reforms, and other civic rulings for the benefit of the public, too numerous to mention.

NURSING.—An important outgrowth of the advance of knowledge as to the cause and prevention of disease is represented by modern methods of tending the sick in hospitals as well as the home. "The advent of *trained nurses* as a feature in the practice of medicine and surgery is of comparatively recent growth, and their training schools have been not inappropriately likened to the latest bud on the tree of evolution. The need for a system of trained workers was expressed nearly fifty years ago by Dr. Gross, when he said that there ought to be in all the principal towns and cities of the Union, institutions for the education of those whose duty it is to take care of the sick and to carry out the injunctions of the medical attendant. The training school of Charity Hospital on Blackwell's Island was one of the first institutions in which this idea took practical shape. It was formally opened on August 1, 1875, with fifteen pupils, whose number was almost doubled within the next following month. Originally established as an experiment, it was not long before the school outgrew the tentative stage and became one of the important institutions of the city. At that time, there were only three similar institutions in the United States: The Bellevue training school for nurses, and those in Hartford, Conn., and Boston, Mass." (Quinlan.)

Systematic nursing in this country first gained a foothold in the early sixties of the nineteenth century, in Philadelphia and Boston, gradually spreading from these centers to other cities. The tendency of the present is to regard the art of nursing as an independent vocation, as an adjunct and auxiliary to medicine. The great clinician v. Leyden, in his address before the Fifteenth Congress of Internal Medicine in Berlin (1897) expressed himself in the following memorable words: "The nursing of the sick, already recognized in its full importance, is rapidly becoming an essential and indispensable branch of scientific medicine."

MEDICAL EDUCATION.—Concerning advances in medical education in the last half century, facts and figures speak for themselves: Medical schools requiring a three years' course did not exist in the United States in 1875, whereas in 1903, a four years' course was compulsory in 144 medical schools. In 1914, a four years' course leading to the degree of Doctor of Medicine was the standard required for admission to membership in the Association of American Medical Colleges. According to the report of the U. S. Commissioners of Education for 1902-3, there were at that time in the United States a total of 146 medical colleges, also postgraduate; of these, 118 were classed as regular, 19 as homeopathic, 7 as eclectic, 2 as physiomedical. In the last ten years the number of medical colleges has been markedly reduced, as the result of a reform movement inaugurated by the American Medical Association. In 28 States, the medical schools are now integral parts of the State University; in 16 States, there are no other medical schools, this branch of education be-

ing entirely in charge of the State University. A collegiate degree or its equivalent is now a condition for matriculation in the leading medical schools of this country.

Medical Education of Women.—Nearly half a century ago, in 1868, the Woman's Medical College of the New York Infirmary was opened by Dr. Elizabeth Blackwell and her sister Emily: it was in existence for thirty years. The need for separate institutions progressively declined as the majority of medical colleges opened their doors to students of both sexes. The Woman's Medical College at Philadelphia (founded in 1850) graduated eighteen students in 1914; in this year, only two medical colleges were in existence for women students exclusively. In contradistinction, there were in 1914 over 54 co-educational schools, including such institutions as the medical departments of Johns Hopkins, the University of Michigan, and Cornell. In the British Isles, women were admitted to the study of medicine in the late seventies of the nineteenth century. Germany lagged behind and did not admit women students to the state examinations in medicine until 1900; in this year, Heidelberg University was opened to students of both sexes. Medical diplomas have been bestowed upon women by the Faculty of Medicine at Paris, as well as by the Swiss Universities of Zürich, Bern, and Geneva. The Spanish universities of Madrid, Barcelona, and Valladolid admit women students to the medical courses. Sweden offers medical courses for women at the Carolinian institutions at Stockholm and at Upsala. Recently, a medical school for women has been founded by the War Department of the Russian Government, in Petrograd.

Libraries.—The tremendously increased literary output of the last decades has necessitated the establishment of medical libraries and index catalogues, unknown and unneeded half a century ago. In 1875, the Boston Medical Library was started as a library association, with Oliver Wendell Holmes as president. The Index Medicus, a monthly bibliography of the world's medical literature, founded in 1879 by Billings and Fletcher, is now indispensable to the profession. Among the medical libraries of all countries the highest rank is usually conceded to the Surgeon General's Library at Washington, which is followed in size and importance by the library of the New York Academy of Medicine and that of the College of Physicians in Philadelphia.

Through modern methods in the compilation of statistics and of clinical records, the treasures of medical and surgical experience are now rendered more generally available than ever before.

The distinctive features of modern medicine are, briefly summarized, the remarkable increase of general knowledge; the progressive interpretation of the vital processes; the inductive methods of the modern clinician; the dauntless advance of surgery; the improved curative procedures, aided by the admirable finish of instruments and apparatus. Modern medicine has undergone a transformation from an art to a science to be acquired by diligence and application, with the result that there is no lack in our day of skilled physicians assiduously working for the relief of human suffering.

Contemporaneous medical thought is dominated by the reformatory influence of the doctrine of Darwin (published in New York in 1871) and by Weismann's work on the continuity of the germ-plasm,

which appeared in 1885. The relation of the natural sciences to science as a whole was discussed by Helmholtz in the latter part of the nineteenth century.

The advance of science in general, and of medicine and surgery in particular, is often held responsible for the materialistic undercurrents in the stream of modern civilization. The injustice of such a charge is most forcibly revealed through this beautiful paragraph from the writings of a great contemporaneous scientist (v. Cyon, 1910) describing his conception of the organic world: "In the absence of scientific proof of the existence of organized beings on other planets, the investigator is justified in regarding this tiny earth as a sort of biological experimental station of our planetary system, its most perfect organism being represented by man. Human delusions are thus efficiently dispelled, in which man believes himself the master of the world, because he laboriously constructs a flying machine on the pattern of a bird, or a submarine boat after the model of a torpedo, which usually afford him the opportunity of destroying himself or his fellows. Science does not even invest man with the supreme control of his own small planet. He possesses the power of adapting the forces of nature to his purposes; the highest goal he can attain as an investigator is the discovery of the laws governing these forces. For so much he is indebted to the Creator of the biological station, who has invested him with a modicum of intelligence and with will-power, so that he may employ his knowledge for the benefit of his fellow-men and for the glory of Almighty God."

F. ROBBINS, M.D.

A RECORD OF ACHIEVEMENTS.

THE following is a partial list of epoch-making discoveries in medicine which the MEDICAL RECORD was the first to announce to American readers (the dates are those of publication in this journal):

Lister's employment of carbolic acid in antiseptic surgery, October 15, 1867.

Esmarch's method of bloodless surgery, December 1, 1873.

Koch's discovery of the *Bacillus tuberculosis*, May 20, 1882.

Prophylactic treatment of rabies by injections of virus, August 19, 1882.

Koch's discovery of the comma bacillus of cholera, March 15, 1884.

Koller's employment of cocaine in eye surgery, October 11, 1884; the first reports of the use of cocaine in this country were made by C. R. Agnew, W. O. Moore, and J. L. Minor in the issue of October 18, 1884.

Intubation of the larynx, February 21, 1885.

Koch's announcement of the preparation of tuberculin reported in the cabled proceedings of the Berlin International Congress, August 9, 1890.

Discovery and experimental use of tetanus and diphtheria antitoxins announced in a special cablegram on December 6, 1890.

Finlay's theory of the relation of mosquitos to the spread of yellow fever, November 24, 1894; confirmation of this theory by the U. S. Army Commission, November 3, 1900.

Relation of mosquitos to the spread of malaria, September 21, 1895.

Roentgen's discovery of the x-rays, January 11, 1896, an x-ray plate of the hand published February 15, 1896.

Cosmetic employment of paraffin injections, April 13, 1901.

Mme. Curie's discovery of radium, May 3, 1902.

Discovery of the dysentery bacillus as a cause of the summer diarrhea of infants in this country, September 13, 1902.

Wassermann reaction described June 2, 1906.

First report of American cases in which salvarsan was given in syphilis, made by M. S. Kakels, September 24, 1910.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

GUNSHOT WOUNDS OF THE CHEST—SIR ROSE BRADFORD'S ADDRESS—HEMOTHORAX, SIMPLE AND INFECTED—MEMORIAL SERVICE FOR LIEUT.-COL. H. B. YATES.

LONDON, Feb. 4, 1916

WE have had a full discussion at the Medical Society of London on "Gunshot Wounds of the Chest." It was opened in a careful paper by Sir John Rose Bradford, who dealt mainly with the subject from the physician's point of view; he was followed by Dr. Morrision Davies with a paper on the surgical treatment, and Capt. H. G. M. Henry, who spoke on the pathology and bacteriology. The discussion was carried on by Col. Hale White, Dr. Murray Leslie, Mr. Cortlandt MacMahon, and Dr. Poynton. Sir J. R. Bradford's opening address dealt with his experience in the base hospitals in France since October, 1914, including many hundreds of cases, not a few of the greatest severity. Many reached the base within two or three days of being wounded, but more did not arrive for a week. A few remained near the front for two or three weeks. Wounds which appear to be confined to the chest wall may include a small entering of the thoracic cavity, and if respiratory symptoms are not well marked the chief danger may be overlooked. Hemoptysis may result from injury to the chest wall, perhaps from bruising of the lung only. Death has followed such injury and no *post mortem* change has been found, thus showing that hemoptysis is not absolute proof of penetration of the lung. Hemothorax also may follow a wound of the thoracic wall without penetration. Pleurisy may be serous or purulent, or again of streptococcal origin. Cases of pneumothorax are not very common, but form a distinct group, having a very large opening; but in some the opening is quite small. In such, situated in the upper chest, a counter-opening is often needed in the lower half. The pleura is generally infected and drainage from the wound imperfect. With perforating wounds of the chest or lung there may be (a) hemothorax, (b) pneumothorax, (c) pneumohemothorax, (d) laceration of lung, leading to abscess or gangrene, etc.

Hemothorax may be sterile or infected, the amount of fluid varying from a few ounces to four or five pints. On *post mortem* the parietal pleura is covered to a considerable extent with fibrinous clot, one-eighth inch, or more, thick; the lower and middle lobes of the lung are collapsed and pressed back toward the vertebra or pushed upward to the root of the lung or inward to the pericardium. On the other hand, the upper lobe is greatly distended and pushed against the anterior thoracic wall. The bloody fluid is really defibrinated blood with mostly some exudate from the pleura, so containing many red cells with perhaps lymphocytes, polymorphonuclear leucocytes, endothelial cells, eosinophiles, and myelocytes in varying proportions. Hemothorax at first causes painful or distressed breathing and cough, and in most cases hemoptysis, but this last symptom may be delayed for two or three days, in which case it may be due to bruising or infection of the lung. Dyspnea is urgent at first, but abates in 24 to 48 hours, though as much blood as three pints may be present, if the patient be kept at rest. The temperature at first may be only 101°

or 102° Fahr. and soon returns to normal, but sometimes may oscillate between 99° and 103° daily if merely expectant treatment is employed. Two groups of these cases are met with, viz.: (1) where paracentesis is followed by immediate fall of temperature and rapid recovery; (2) where the temperature is not lowered until late, though no bacteriological infection is found. It may be two or even three weeks before normal temperature is reached, but no further operation is required. The physical signs are not precisely like those of pleurisy, but, of course, there is a good deal of similarity. Sir R. Bradford found the most striking fact in cases examined at the front within 24 hours of the injury was the absence of well-marked signs with severity of the symptoms. Displacement of the heart and poor entry of air on the affected side, but not decided dullness of percussion; 24 hours later the case may present the typical signs of extensive hemothorax with perhaps considerable subsidence of urgent symptoms. Bulging of the affected side with scarcely any movement, apex beat displaced somewhat, but not solely, in degree corresponding to the amount of effusion. Vocal fremitus diminished below, increased above the distended lung. Percussion short, dull, high-pitched over the effusion, but well marked above. Auscultation over lower chest gives weakness or even absence of breath sounds; or they may be harsh and bronchophony and pectoriloquy, leading to erroneous diagnosis. The most common mistake is to confuse with pneumonia, as in both there is hurried breathing, pyrexia, and bloody expectoration.

As to treatment, Sir Rose Bradford in the earlier months of the war relied on expectant methods, owing to a supposed risk of secondary hemorrhage, and the cases did fairly well, but were long in regaining health. Serious collapse of the lung also ensued rather often, but not secondary hemorrhage. Aspiration with replacement by oxygen to avoid too sudden expansion was employed with two distinct benefits: the lung rapidly reexpands and the pyrexia subsides, patient quickly recovering and his invalidism being measured by weeks rather than months. The replacement by oxygen is most valuable; it enables all the fluid to be removed at once and a second operation is scarcely ever needed, though it often is with simple paracentesis.

Infected cases of hemothorax were about 25 per cent. of those seen at the front, and in 20 per cent. of them the infection was derived from the lung, i.e. the fluid contained lung organisms. The clinical picture may differ little if at all from non-infected cases, so that diagnosis cannot be certain except by exploratory puncture. But usually pyrexia, dyspnea, and icterus are well marked and the patient is very ill, though sometimes at first this is not obvious and later urgent symptoms suddenly set in. Other cases are associated with anaerobic infection and may be mistaken for pneumothorax; others again of a severe type are associated with streptococci and may be complicated with pleurisy, pneumonia, or pericarditis. Mortality in septic cases is reduced by recognition of the presence of the organisms and prompt drainage.

Surgeon-General Carleton Jones, honorable surgeon to H. R. the Duke of Connaught, governor-general of Canada, represented his Royal Highness at the memorial service for Lieut.-Col. H. B. Yates at the Church of St. John of Jerusalem in England, of which order Colonel Yates was a Knight of Grace.

1. **Skin Reactions by Various Bacterial Proteids in Certain Vasomotor Disturbances of the Upper Air Passages.**—J. L. Goodale states that it has been shown for years that an individual sensitized to a given protein may exhibit a characteristic reaction, if the protein be brought into contact with the mucous membranes, or introduced below the epidermis in sufficient concentration in a soluble form. While two clinical groups are recognized, the seasonal, as illustrated by hay fever and hay asthma, and the perennial, producing vasomotor disturbances at any time of the year, he desires to call attention to a third group of vasomotor disturbances, which may be termed infections, because their appearance seems to stand in relation to bacterial invasion of the upper air passages. In individuals of this class an immediate and characteristic reaction is elicited by the application to a scratch of the skin of *Staphylococcus pyogenes albus, aureus, citreus*, and *Micrococcus tetragenus*; also by an unidentified bacillus having some of the characteristics of Friedlander's bacillus. The reactions to these organisms are not equal in all individuals. Certain cases of vasomotor disturbance clinically indistinguishable from the above showed no reaction to the organisms tested, and individuals without vasomotor symptoms developed no reaction in any case. It remains to be shown whether the vasomotor symptoms are due in these patients to an infection of the mucous membranes by the organism which produced the reaction on the skin. It is conceivable that the patients may have been sensitized to the special organism by a previous infection of the skin or mucous membranes. Further study is necessary, according to Goodale, and examinations should be made before, during, and after an attack with the organism suspected, to observe whether a variation exists in the intensity of the skin reaction at different periods parallel with the degree of immunity of the individual.

3. **Abnormalities of the Heart in Infectious Diseases.**—Clifford S. Chapin considers that in studying the state of the circulation in febrile conditions it is necessary to bear in mind three facts, viz., that the heart's action is modified by increase in temperature, that the heart reacts differently according to the toxins produced by the agent causing the fever, and that the heart itself may be the seat of the conditions. Recent researches demonstrate the invasion of the heart by the specific organism in rheumatic fever, pneumonia, typhoid fever, diphtheria, erysipelas, influenza, and septic infections. The results are shown in the occurrence of endocarditis, myocarditis, and pericarditis. The symptoms which follow are not always distinctive, and may resemble the symptoms induced in the heart by febrile conditions alone, or by toxins produced from other sources in the body. Writers usually describe separately the symptoms of endocarditis, myocarditis, and pericarditis; in reality the symptoms described are not manifestations of endocarditis and pericarditis, but are the signs of a myocardial affection. Endocarditis and pericarditis, both acute and chronic, bulk so largely in medical literature because an abnormal sound in-

variably impresses the mind to a greater extent than an abnormal sign perceptible by the other senses, and the easy recognition of the valvular murmur, and the friction sound has led to the associated symptoms being ascribed to the same lesion. The simple febrile heart shows little change at first beyond having its rate abnormally accelerated by exertion. The sounds are clear and distinct, and there is no increase in size; but with long continuation of fever, a certain amount of dilation may arise, usually on the right side of the heart. In myocarditis, the most characteristic evidence of damage done to the heart muscle is the irregularity of pulse intermission, due to dropping out of ventricular systoles, because of lesions in the auriculo-ventricular bundle. Changes are also found in the size of the heart. Passing on to endocarditis, the only direct evidence of an acute condition is the presence of murmurs at one or other orifice of the heart. Two murmurs are to be considered, viz., a mitral systolic murmur and an aortic diastolic. It is not always easy to tell whether the appearance of a murmur during a febrile attack is due to involvement of the mitral valve in an endocarditic process, or to the relaxation of the muscle supporting the orifice. A diastolic aortic murmur is, as a rule, diagnostic of the involvement of the aortic valve in some destructive process, and, at first, is so faint that the sound does not end with sufficient abruptness. Later this changes to a short whiff at the end of the second sound. Murmurs due to endocarditis are not definitely recognized until after the subsidence of the fever, when the sclerosis sets in. The presence of a musical murmur may be assumed, in acute cases, to be due to a vegetation. In pericarditis dependence has to be placed upon the to-and-fro murmur produced by the movements of the heart, and it is often accidentally discovered. This condition may be caused by chronic complaints, such as diabetes and Bright's disease, as well as from the infectious conditions. Very little embarrassment is felt from pericardial effusion, due to the fact that the normal pericardium is a more or less inelastic bag, and, with the inflammatory invasion, becomes distensible and able to accommodate an enormous amount of fluid with little inconvenience to the heart. The most formidable conditions are met with in relation of the heart in rheumatic fever. The chief lesions in man are: acute dilatation, endocarditis, and pericarditis. As the damage done is a complex one, the term "carditis" is applied to this condition. The most serious form of heart disease in rheumatism, next to malignant endocarditis, is pericarditis—not particularly on account of its intrinsic harmfulness, but on account of the severe type of infection which accompanies it, and the involvement of the myocardium. It is more frequent in childhood than in adult life, and the most characteristic examples occur in the first week of the attack, but there is no period when it may not occur. Attacks of rheumatic fever may complete their course with no heart complication, or the heart may be affected and give no positive sign. It may be only after months or years that any indication will present itself of heart involvement, which the symptoms of the subsequent process of sclerosis may have revealed. While a heart complication in pneumonia may reveal itself by sudden collapse of the patient there are two conditions which are of grave import in this disease—the occurrence of an occasional irregularity before the crisis, and a pulse rate of over 140 per minute. However, neither of these is a necessarily fatal symptom. It is in diphtheria that Chapin considers the heart sequellæ to be most varied and dangerous. The conclusions he draws with reference to this condition are of great importance: the frequency of heart murmurs and irregularity of the pulse;

moderate disturbance of the heart, while severe complications are infrequent. Frequent examinations of the heart are necessary because of the marked changes in rhythm from one hour to the next. Gallop rhythm, late vomiting, and epigastric pain and tenderness are important as danger signals of severe heart complications. Antitoxin does not affect the heart unfavorably, and its early use prevents the appearance of grave heart lesions. Bronchopneumonia is a more frequent fatal complication than heart disease; sudden death from heart condition is very rare when patients are kept in bed for a proper period. Prolonged rest is necessary in all cases, but should be governed by the stage of the illness and the general condition. Heart murmurs and irregularity are of long duration in many cases and should be watched for some time after convalescence has set in. Endocarditis and pericarditis are special complications in scarlet fever, and are covered by the septic and simple or toxic types. The heart cannot be said to show any changes peculiar to typhoid fever. Dilatation may be present, but is not often marked, and is more common on the left side. In acute diseases due to some infective agent, the prognosis depends upon the nature and intensity of the infection, and judgment must be suspended until the cessation of the active lesions in heart conditions. If the heart has resumed its normal aspect, size, rate, and rhythm, the damage has been slight and the outlook hopeful. If some evidence of damage persists, it must be watched to prevent the presence of low inflammatory conditions which lead to the formation of fibrous changes. When the real nature of the trouble is appreciated it will be realized how powerless is the effort to modify the disease process.

5. **Diathermia; a Physiological Specific.**—Albert C. Geyser defines a specific in medicine as an agent which has a selective, curative influence on an individual disease. Every attempt at repair or recovery is essentially a physiological response on the part of the uninjured cells. This response or inflammation may embrace many phenomena, but the essential one is heat. With heat all of the various manifestations may be present, while without it not one can manifest itself. Heat must not be applied from the outside, as that would be heating the tissues by contact and conduction of radiant or thermic energy. What is needed is to have a physiological specific that will cause a functioning of all the deeper-lying tissue, which will express itself in the production of heat, and this heat must originate from within and be conducted outward, and not applied externally. It must be the result of cellular activity responding to a nonpathological stimulus. Such an agent is to be found in the high-frequency current, with its millions of alternations a second when applied for diathermic purposes.

6. **The Clinical Significance of a Gastric Analysis.**—Louis Winfield Kohn calls attention to the fact that in affections of the gastrointestinal tract every effort should be made to first determine the immediate causes of the symptoms and then afterward to seek the true primary cause. A means which suggests itself for this purpose is gastric analysis, which consists of a macroscopical, microscopical, and chemical examination of the contents of the stomach recovered by the stomach tube

following a period of fasting as well as after a test meal. He refers especially to the fasting stomach test, which consists of an examination of the stomach contents of a patient who has denied himself or herself any food or nourishment for a period of ten or twelve hours. By this method motor disturbance can be recognized as directly or indirectly concerned with gastrointestinal affections. As ordinarily performed, the patient is instructed to eat a small plate of rice cooked in milk (about six tablespoonfuls) at 9.30 P.M., and then to avoid food or drink until 9.30 A.M. the next day, at which time the stomach contents are drawn off through a stomach tube and examined macroscopically, microscopically, and chemically. Macroscopically, the residuum is examined for color, consistency, reaction, odor, and amount. In true higher grades of motor disturbance, such as pyloric obstruction, malignancy, and hourglass contractions, etc., a larger precipitate is found containing food particles taken into the stomach several days before the test is made. Microscopically, red and white blood cells, epithelial cells, free nuclei, salivary corpuscles, and mucus may be found in proportion to the condition causing the trouble and indicative of it. The chemical test is not so important, but, in addition to the foregoing tests, assures a more correct diagnosis.

5. **Thromboplastin (Tissue Extract) as a Hemostatic.**—John J. Cronin gives an account of the method employed for the removal of tonsils and adenoids at the five clinics under the supervision of the Bureau of Child Hygiene, Division of Children's Clinics, New York City. The clinics have been carried on since March, 1912. For about six months horse serum was employed to prevent hemorrhage, with fair success. In October, 1914, the writer, with T. Joseph Barry devised a combined operation, which while simpler than the former method of procedure, did not overcome the capillary oozing from the nasopharynx. About this time the writer's attention was called to an article by Alfred F. Hess with reference to thromboplastin as a hemostatic, and he immediately began the use of thromboplastin after the removal of the tonsils and adenoids, by applying it to the denuded surfaces. The results were striking. The patients showed only a little bloody saliva after being put to bed, healing was expedited, and many patients were entirely well at the end of four days. Thromboplastin was introduced into all the department of health rose and throat clinics with remarkably good results. The technique of the preparation of thromboplastin is as follows: Fresh ox brains are obtained from the slaughter-house, stripped of their membranes, washed in running water, and weighed. They are then

passed through a meat chopping machine three times, and an equal amount of normal salt solution is added. This suspension is allowed to remain in the refrigerator for forty-eight hours, then it is twice pressed through cheese-cloth. This extract is diluted with one-half its quantity of salt solution. Tricresol is then added in proper proportion so that the finished preparation contains 6.3 per cent. The fluid remains sterile, and maintains its hemostatic potency for months.

6. Epidemic Cerebrospinal Meningitis Developing Twenty-Two Hours After Abdominal Operation.—Lewis M. Gaines reports a case seen in consultation with Charles M. Remsen. The patient, a woman of 30, had been operated upon by Remsen for an abdominal condition on the previous day. On the morning of the operation the patient appeared normal, having no clinical signs. In the evening, hours after the operation, there was some vomiting, but general condition was satisfactory. The following day, after a restless night, a general epileptiform convulsion occurred lasting ten minutes. There were no prodromes, and the seizure appeared out of a clear sky. This was followed by a second convulsion, at 12.40 P.M. Coma had existed from the first convulsion. There was at this time no signs of meningitis, except that the pulse showed startling changes and the respiration became very irregular. Lumbar puncture was done the day following the operation, and 10 c.c. of a slightly turbid fluid withdrawn, which showed a small number of extracellular meningococci. Thirty c.c. antimeningococcic serum were at once administered intradurally. This treatment was continued and about a month later the patient was able to walk with assistance, speech was normal, and memory regained. Except for slight emotional disturbances, there were no symptoms. Gaines points out the following interesting features of this case: (1) The occurrence of cerebrospinal meningitis as an operative complication. (2) The entire absence of the physical signs of meningitis for twenty-four hours after the initial convulsion. There were no Kernig's sign, no ocular manifestations, no prodromal headache, no disturbances of temperature until eight hours after the initial convulsion, and none of pulse or respiration until twelve hours after the initial convulsion. The only symptoms for a number of hours were convulsions, muscular twitchings, and coma. Diagnosis was made as the result of lumbar puncture. (3) The probability that meningococci were present in the purulent material in the nasal passages, and the interesting and unsolvable problem as to whether or not the anesthetic had anything to do with the passage of organisms into the meninges (mechanical factors, lowered resistance). (4) The nonunion of the operative wound until after the complete subsidence of the meningitis. (5) The remarkable curative effect of the Flexner serum given persistently, in a case in which, for a number of hours prior to the first dose, the patient appeared moribund.

9. Syphilis of the Stomach.—George M. Niles gives a report of a case in a young man, aged 28, referred to him for regurgitation of gas, nausea, frequent vomiting, distress after eating, a continuous sensation of weight in the epigastrium, and an excruciating gastralgia. These symptoms had begun six months previously, and the past history proved uneventful with one exception, a small sore on the penis when the patient was 21 years of age. This sore, having readily healed under local application, was almost forgotten. The patient was somewhat cachectic in appearance, was losing in weight, and there was fear of cancer of the stomach. Physical examination was negative, gastric analysis showed absence of both free and combined hydrochloric acid, while a trace of lactic acid was

present. A roentgenogram disclosed a distorted stomach evidently due to intragastric new growth. Wassermann test was 4+. The patient was put on antisyphilitic treatment, improvement began, and at present a report is given of comfortable and normal digestion. The interesting feature of this case, according to the writer, was the difficulty in differentiating between syphilis of the stomach and cancer of the stomach.

2. Preliminary Note on the Use of Gynocardates Orally and Subcutaneously in Leprosy.—Leonard Rogers states that chaulmoogra oil has maintained its reputation as the best known remedy for leprosy, although it is so nauseating and interferes with digestion so much that only rarely can it be borne in sufficient doses to be more than a palliative in this obstinate disease. On this account he has used for a number of years and recommends gynocardic acid (also known as chaulmoogric acid, and believed by many to be the active principle of the oil) in place of chaulmoogra oil, which contains a large proportion of almost useless palmitic acid. He gives a report of three patients who, among many, have been able to tolerate large quantities of gynocardic acid by mouth; and in whom was shown remarkable improvement in the course of a year or two. For hypodermic injection the sodium and potassium salts were used, as gynocardic acid was unsuitable on account of its insolubility. While the salts dissolved readily in water, the potassium salt proved to be the more readily dissolvable, but not so convenient, due to its buttery consistence. The gynocardates obtained from the various sources mentioned all gave the typical reaction of chaulmoogra oil with sulphuric acid—namely, a brown color changing to green. The best results were obtained in the nerve cases, one of which improved rapidly under large doses of gynocardic acid internally, and injections of gynocardates of sodium twice a week in from one to two grain doses. This treatment was followed by marked diminution of the anesthesia, and return of heat and cold and tactile sensation, as well as some gain in muscular power within two months, although his condition had been practically stationary for several months previous. In several other cases ulcers have healed, although in one case some new ones developed on the finger during the injections—possibly a local reaction. The considerable degree of success reported after two years' intramuscular injections of the oil makes the outlook hopeful that the less painful injections of the gynocardates may ultimately prove to be a more rapid, effective, and convenient method of treating this most distressing disease.

3. Two Cases of Fourth Disease with Relapse.—Oswald J. W. Adamson reports two cases, both military men, who at about the same time—being in the same unit, but living in different huts—were admitted to the isolation ward of the Lydd Military Hospital suffering from a condition later diagnosed as fourth disease. These cases both experienced a relapse from two to three weeks after the initial attack. In considering these cases the question arises of a satisfactory diag-

nosis between scarlet fever, German measles, and fourth disease. Against scarlet fever may be mentioned the long invasion period (four days instead of one), the fact that the pulse was in proportion to the temperature,—in scarlet fever the pulse is disproportionately high,—the involvement of the inguinal group in the glandular enlargement, the absence of circumoral pallor, albuminuria, and vomiting, and the presence of conjunctivitis in one case, the small degree of faucial inflammation, and the occurrence of pleurodynia as a premonitory symptom. Against German measles may be mentioned the absence of enlargement of the posterior cervical glands, the severity of the malaise, the headache and pains, the degree of desquamation (this being rarely present in appreciable degree in German measles), the seasonal incidence, the strawberry tongue in one case, and the fact that neither case had a rash such as one usually meets with in German measles. Adamson points out the peculiarity of these two cases, which, according to his experience, does not occur either in scarlet fever, German measles, or fourth disease—the relapse and recrudescence of fever. His explanation of these relapses is that both cases were exposed to infection at the same (unknown) time. Both entered the invasion period about the same time, but the first patient showed premonitory symptoms (for which he was admitted to the hospital), whereas the second did not. Both patients had two relapses, the second coming at the same time in both cases, while the first did not. As there was no scarlet fever or German measles in camp, the question of one or both of these relapses being some other disease hardly arises.

5. The Examination of the Soldier's Heart.—O Leyton records some observations based upon a method of investigation which does not appear to be generally recognized, or, if recognized in the past, may have been believed to possess such limited application as to have fallen into disuse. It may prove of great value in determining the extent of disease of the myocardium in cases of "soldier's heart," in assisting in prognosis, and in the detection of malingering. The normal ratio of intensities of the first sound at the apex to the second sound at the base is approximately 2 to 1. Experience has shown that this is altered in myocardial disease. In quite a number of cases, the ratio of intensity is altered before there is any tendency toward alteration in the strength of the beats of the heart. For this purpose the Bock stethoscope is the most practical one. The principle upon which this stethoscope acts depends upon diminishing the size of a hole in a thick diaphragm through which the sound must pass from the chest to the ears of the observer; the size of the hole is altered by screwing a cone-shaped piece of metal into it. The stethoscope is arranged to read 100 when the hole is completely closed, the face of the stethoscope is divided into 100 divisions; in order to use it the pointer is placed at 10, the stethoscope is applied over the heart, and the pointer slowly turned clockwise until the first sound can no longer be heard. The average position, when examining a normal individual, is about 80. The reading is made several times and an average taken. The stethoscope is then placed over the aortic site, and is again opened to 10, then gradually closed until the second sound cannot be heard. In the average individual this will occur about 45, and the ratio of intensity may be represented by 80 to 45. The instrument cannot be used when there are cardiac murmurs. The cases presenting the symptoms of "soldier's heart" following explosions have not shown any evidence of disease of the heart, and they have been considered of nervous origin, as the ratio of the sounds has always been 2:1, *i.e.* normal.

2. On the Immediate Treatment of Severe Post-Partum Hemorrhage.—R. K. Howat classes cases of post-partum hemorrhage into three groups, according to their causes, namely: 1. Laceration of the parturient canal. 2. Retention of the placenta (partial or complete) within the uterus. 3. Inadequate shrinkage of the uterus. These causes in turn indicate the appropriate lines of treatment which may have three successive objects: 1. The immediate arrest of the hemorrhage. 2. The immediately succeeding maintenance of this arrest. 3. The permanent closure of the bleeding vessels. While the general principles of treatment are the same for all cases, the particular means employed for the first and second objects may depend to some extent on the severity of the hemorrhage in the particular case, and the same means can promote both objects. The third object is attained by purely natural means, the formation and growth of new tissue. The first two causes can be handled without great difficulty, the first requiring surgical skill, and the second a careful inspection of the expelled placenta and palpation of the uterine interior. It is the post-partum hemorrhage from uterine flaccidity after expulsion of the placenta which presents the gravest danger. Here is no dramatic violence compelling attention as in the case of surface wounds. There is no pain to enforce complaint, as in ruptured tubal pregnancy, and this hemorrhage, occurring under the bedclothes, is unseen. The patient is at first only aware of a warm discharge, which she has no reason to suppose is not quite natural. She soon feels faint, and almost immediately is beyond the power of speech, perhaps dying. A situation like this demands a simple, direct, efficacious, and easily applied line of treatment which the physician should have thoroughly in hand. Since the majority of confinements take place in modest homes, where assistance is relatively slight, the essentials of treatment must be independent of all but the most primitive accessories. Howat offers the following procedure. The patient's appearance suggests the condition present, and the blood present clinches the diagnosis. With one hand the abdominal aorta is compressed, requiring about three seconds. Meanwhile the nurse is called to the bed. The other hand separates the thighs and is passed into the vagina. The cervix is felt and grasped with moderate firmness in order to steady it and so help the other hand in its next move. Then the abdominal hand, leaving the aorta for the moment, "gathers" the relaxed and blood-filled uterus in its hollow, squeezes it, and presses it down in an anteflexed position against the vaginal hand, which meanwhile has been shut and moved into the anterior vaginal fornix. The anterior and posterior uterine walls are now pressed against each other by the two hands. Pressure can also be made at the same time on the aorta by the back of the wrist of the abdominal hand. While this is being done, a pillow is placed between the

patient's head and the top of the bed. As soon as the uterus is grasped between the hands, the nurse lifts the patient's pelvis to an angle of 60 or 70 degrees with the bed—the patient is put in a low Trendelenburg position. Pillows, inverted chairs, or a towel or sheet hung from the bed-top can maintain this position and the nurse is relieved. No other local treatment is necessary. If low blood-pressure be present, the patient's arms and legs are raised to the vertical and held there by assistants. When the uterus is felt to be firmly contracted the vaginal hand is withdrawn and a wet pad is placed to the vulva. As soon as the general conditions are satisfactory, the pelvis is lowered to an angle of 30 degrees and the abdominal hand removed. A binder is tightly applied, and the patient is kept in this elevated position as long as desirable—never less than several hours. Whatever additional measures may be thought necessary are applied and suitable arrangements made for the patient's general comfort.

4. The Influence of Syphilis on the Chances of Progeny.—N. Bishop Harman in investigating the case-papers of over a thousand children whose blindness was the effect of parental syphilis obtained the family history of 150 families—that is, the history of the mother with relation to the number of her pregnancies and the results of them. In each of these families one or more of the children were undoubted sufferers from inherited syphilis. Besides the bone or joint conditions, Hutchinson's teeth were present in no less than 68.5 per cent. in the blind child of the family. Among eleven families to which only one child was born there were four illegitimate unions and the progeny therefrom; all these eleven were blind children and alive at the time of inquiry. Harman says that the history of these 150 families set out by themselves would provide a characteristic picture; and as compared with the history of 150 healthy families, the contrast is extreme. The comparison was made and the difference between the results of the fertilization of these two sets of women is remarkable; 150 syphilitic mothers had no fewer than 1,001 pregnancies, but of these only 390 resulted in presumably healthy children. On the other hand, 150 healthy mothers had 826 pregnancies, from which resulted 654 healthy children. The syphilitic mothers had about 17 per cent. more pregnancies than the healthy mothers. It is unnecessary to point the moral, the author says, for the figures speak sufficiently of the influence of parental syphilis on the chances of healthy progeny.

11. Relapsing Beriberi.—J. C. McWalter reports the case of a patient, a soldier, about 28 years old, on sick leave. He had contracted beriberi in India. His diet was the regulation army fare—meat, vegetables, milk, bread and butter, tea, and occasionally a bit of rice or sago pudding, but at no time in his life was he ever on an exclusive or continuous rice diet. This rather opposes the accepted view that beriberi is due to lack of vitamins produced through the consumption of quantities of polished rice, which is deficient in vitamins. He had exhibited the usual symptoms of the disease—multiple peripheral neuritis, considerable weakness, cardiac dilatation, and edema of the legs, etc. Under treatment for some months in bed, he improved, but signs of cardiac dilatation with a definite bruit remained. During the periods of remission no physical sign of the disease could be seen, except the evidence of cardiac dilatation. The usual cardiac tonics, as iron and digitalis, apparently afforded some relief to the heart trouble, but nothing that was given, the author said, seemed to have any effect specifically on the beriberi.

Berliner klinische Wochenschrift.

January 10, 1916.

Treatment of Infected Bone and Joint Wounds.—Körte states that these wounds give trouble enough even under the most favorable conditions; since there must be prolonged suppuration and fever, why does infection so frequently occur? Dry, warm summer weather is no preventive, although results are better under favorable climatic conditions. Prolonged warfare with its hardships and lowered resistance favors infections, yet this, too, occurs among young and fresh recruits. Trench fighting and lack of care of the body decidedly facilitate infection. Since the bullet itself is sterile it has to shove dirt, etc., into the body to produce infection. In bullet wounds of bone, the blood shed about the bone fragments supplies a superior culture bed for pathogenic bacteria. Hence whenever the entrance and exit wounds are small and slot-like they should be sealed up in the hope of excluding micro-organisms. Of other factors in infection may be mentioned prolonged lying on moist, swampy soil before the dressings can be made; lying on straw after imperfect first aid dressing; improper splinting, or other fixation, and premature transportation, and without proper supporting dressings. On the Eastern battle line, in Poland and Litau, facilities for the first sojourn are very poor and it often happens that the wounded must be bedded on dirty straw for days at a time; i.e., the straw is at first clean, but soon becomes contaminated. This drawback necessitates great care in dressing the wounds and changing the dressings of discharging wounds. In the latter the change must be made promptly. Adhesive dressings are to be avoided in favor of plain gauze strips carefully wound. There must be fixation of any limb which is the seat of a bullet fracture. In regard to prevention and treatment the author in addition to incision and drainage of shrapnel wounds recommends a mixture of phenol and camphor, 1 to 2, in small quantities, talcum containing 10 per cent. calcium chloride and equal parts Peru balsam and spirits. The attempted disinfection of wounds by the use of saline infusion, glucose, hypochlorate of sodium, magnesium chloride, etc., as practiced by English and French surgeons, is mentioned without much comment.

Some Indications for Venesection.—Theilhaber mentions the recent revival of venesection in medical literature, and cites a recently published article on this subject by Engelhorn (he is silent concerning the recent monograph by Heinrich Stern of New York, which has been published in both German and English). The abrogation of this practice conforms closely to the latter half of the nineteenth century, but the rejuvenescence now in evidence appears to show that this negative period represents a gain only through the breaking up of the routine tendency to bleed. The new indications correspond largely to the best of the old. Engelhorn has bled for the climacteric and for dysmenorrhea, and these conditions demand a series of bleedings, or, in other words, phlebotomy is raised to the dignity of a system of treatment. The author finds the letting of a little blood a good remedy for nervous headache in which we may assume the existence of a congestion of some of the sensory nerves. Naturally anemia is a contraindication. Of great interest is the suggestion to bleed those who have recently recovered from cancer operations. Animal experiments show that bleeding causes a marked stimulation of the bloodmaking organs. This was recommended a century ago by Bayle. The author would bleed every six months and combine the resource with the usual physical remedies. There

is reason to believe that the newly formed blood antagonizes the reappearance of the cancer.

Muenchener medizinische Wochenschrift.

January 11, 1916.

On the Fate and the Action of Hot and Cold Drinks in the Stomach.—Egan states the old experience that cold drinks on an empty stomach may cause unpleasant sensations in individuals with affections of the stomach, liver, and gall ducts. Some patients may complain of pain, although others with the same ailments experience nothing unpleasant. In fistula cases whether hot or cold water is swallowed the temperature is said to be soon equalized. The claim has also been made that very cold water causes reflex closure of the pylorus, thus preventing chilling of the entire intestine; but this has not been borne out by animal experiment. The unsatisfactory state of our knowledge of the subject has influenced the writer to study it afresh, with radiographic control. A contrast drink consisting of a barium sulphate suspension in milk and starch, which is unaltered by temperature changes, was employed for the purpose. The extremes used were -2° C. and 55° - 57° C. In no case was the temperature a source of harm. For sufficient reasons the fluid was introduced by the duodenal tube, instead of by swallowing. It was possible by this method to withdraw the fluid at any time and substitute another. The amount introduced was invariably 100 c.c. All sorts of clinical material was utilized—young, healthy soldiers and the usual run of walking patients. The olive tip of the duodenal sound appeared in the radiogram, along with the contrast fluid, which was injected through the duodenal sound. After sufficient observation the fluid was siphoned out and the tube withdrawn. The summation of the work and results is as follows: the velocity with which drinks, shortly after their arrival in the completely fasting stomach, are again expelled depends wholly upon the individual kind of initial evacuation possessed by the stomach in question. This is not at all influenced by temperature differences, however notable. Water of the temperature of 0° C. as well as of 57° C. leaves the stomach at the same time. There is no activity on the part of the stomach in moderating the temperature. Again, in both the healthy and those affected with gastric disturbances there are those whose reaction to warm water differs from that to cold water. The latter is seen to cause stomach contractions of deep character, while warm water elicits only a superficial wave-motion. Such cases represent a minority, but are constant in their behavior. No rationale could be made to account for the two types, but the knowledge acquired will be of service in accounting for certain chemical phenomena.

Notable Cases Seen in Pediatric Practice.—Ochsenius, a pediatricist of Chemnitz, states some cases of unusual interest seen by him in the past five years. The first was a case of generalized vaccinia in a rachitic child of two years. The four inoculation pustules pursued a normal course, but after vaccination, there was fever and new pustules appeared over most of the surface, with four pustules on the tongue, two of which occupied the tip. The organ became greatly swollen, so that for several days the child lived on liquid nourishment. The author can find no mention in recent classic works of vaccinia of the tongue. Another case was one of measles occurring in a six-year-old boy. Not long before the outbreak of the disease, a brother had slapped his face so hard that the print of the hand remained on the surface. When the rash appeared soon afterward it was partly manifested by an area which

corresponded exactly to the palm and fingers of the offending hand. The phenomenon was only an illustration of a general law that a measles eruption is often strongly influenced by mechanical factors.

Deutsche medizinische Wochenschrift.

January 6, 1916.

Etiology of Weil's Disease.—Hübener and Reiter contribute the sequel to a paper published on this subject last fall. In the meantime their original findings have been confirmed by Uhlenhuth and Fromme. As it now stands the disease can be transmitted at will to guinea-pigs (the question is not yet settled for rabbits), while mice and rats are refractory; the virus is intensified by passage and the urine is rendered infectious; animals with the disease do not infect one another spontaneously; relapses are probably not infectious; atoxyl and salvarsan have practically no power over the disease; immune bodies are formed during convalescence. The present paper, which is brief, deals with the micro-organism of the disease, first described by the authors in September 1, 1915. They have since named it the *Spirocheta nodosa*. Studies of the liver in a disease as characterized by jaundice have, as might have been supposed, proved of the greatest value. Guinea-pigs that have long survived inoculation continue more and more to develop icterus. Smears from the livers of these animals show very delicate spirochetes which stain readily with Giemsa. They show considerable difference in form and grouping, with the nodulation which is commemorated in the name. The nodules appear with especial prominence in a smear stained according to Levaditi, which also shows a coiling of the spirochetes into clumps. The germ has some affinity for the liver cells, and is found only sparsely in the lungs, bones, and spleen. It is present in slight degree in the circulating blood, but hours may be required before a drop of blood will show their presence. The accumulation of the organisms in the liver may be regarded as protective.

Agonal Thrombosis.—Ribbert refers to cardiac thrombosis in *extremis*. He first mentions the so-called postmortem coagulation in the heart and great vessels and the need and methods of distinguishing this clot from a primary cardiac thrombosis. The latter is rounded, circumscribed, adherent to the heart (from which it cannot be detached in mass). The "postmortem" clot is not adherent to the endocardium, save for the trabeculæ and valvular ligaments. The free surfaces of the clot and thrombosis differ notably in appearance. Nevertheless, attention has been recently called to cases in which the free surface could not serve for discrimination. In such cases a diagnosis can be made by tearing apart, for the postmortem clot when torn is tenacious and stringy and yellowish-white. The mystery of coagulation is, of course, bound up in the great individual variations shown in cadavers. In very rare cases the blood is fluid, and as a rule the two forms of the postmortem clot—the red crust and the almost colorless deposit—are present in varying degrees, one kind often greatly predominating. The author now makes an intensive study of the rôle of the red and white cells, platelets, fibrin, etc., in the act of coagulation in connection with the heart and greater vessels and reaches the conclusion that a true postmortem coagulation does not occur, and that what we understand by this term is an intramortem or agonal phenomenon. It is one of the processes of the act of dying. Essentially it lies midway between pure coagulation and thrombosis formation, although it partakes more of the latter than of the former.

Insurance Medicine.

How Shall the Waist Measure Be Taken?—Two measurements taken respectively by two different examiners gave different values on August 4 and August 16. The earlier figure was 110 cm., the later 98 cm. How is this discrepancy to be explained?

The examiner who obtained the larger figure doubtless took a strictly horizontal measurement, which made the tape go around the depressed navel, this depression having been due to accumulated fat. Thereby the tape was made to include the hip bones, so that the figure 110 cm. was obtained. The other examiner, measuring at the level of the lower lumbar vertebra, passed the tape above the navel. It is only in the lean subject that the navel serves as a guide for the waist measure. The tape is passed at the level of the navel in front and lowest lumbar vertebra behind. In the fat applicant the navel is displaced downward, so that two courses are open—either to decline the tape to conform to the navel or measure on the level and include the hip bones.

This question having been referred to the author, he decided that in all cases the tape must rest upon the lower lumbar vertebra, while the two ends must pass directly over the ileum to meet at the navel.

This measurement must be taken during the pause for breath, and the applicant must not attempt to retract his abdomen.

An exception can be made only in a high degree of pendulous abdomen, especially in women. Here, however, special conditions are present which require special mention in the application and cannot be disposed of merely by taking the waist measure. —*Blätter für Vertrauensärzte der Lebensversicherung*, September-October, 1915.

Rara Avis.—Mr. D——. was insured at the age of 43 as a first class risk in all respects. The examiner described him as well-nourished without corpulence. At that period body measurements were not required. The abdomen was described as soft without prominence. The father had died at 38 of "nervous fever," but the mother and several other children were living and well. The applicant had never had but one disease, a "gastric-nervous fever."

Nine years later he made application for more insurance. In the meantime he had become a restaurant keeper. The agent represented him as a risk in no wise inferior to the original status. The medical examiner made a different report. There had been a great increase of girth, which was now 127 cm. (the height was 171 cm.). The chest measure was 109-107 cm. (but 2 cm. expansion). Deep breathing was impossible. Nevertheless the organs appeared to be normal. The simple corpulence had apparently resulted from a greatly increased beer consumption incidental to his occupation. The examiner had scruples about recommending him for increased insurance.

The medical director promptly refused him, stating that it was regrettable that such a risk had obtained insurance in the first place, and that certainly no further risk would be taken with the obese Colossus.

Twenty-seven years have now elapsed. D., who had been living as a successful retired restaurateur, has just died of apoplexy at the age of 79. The family physician reports to the company that for nine years past he had treated the deceased for cardiovascular disease. The patient had

also suffered intermittently with digestive disturbances. On the day of his decease he had risen in apparently excellent health and spirits and had eaten his noon meal. Soon after he was stricken with apoplexy to which he succumbed in two hours. —*Blätter für Vertrauensärzte der Lebensversicherung*, September-October, 1915.

"Accident"—Operation for Appendicitis.—An accident policy insured against "bodily injury sustained through accidental means and resulting directly, independently, and exclusively of all other means in death." The assured was operated on for appendicitis, the wound closing in due course. Matters progressed favorably apparently without complication for four or five days, when he had a fit of vomiting, and the wound opened, the assured dying thereafter under an anesthetic while the wound was being closed again. It was held that there could be no recovery for the death.—*Stokely v. Fidelity & Casualty Co.*, Alabama Supreme Court, 69 So. 64.

Mortality of Typhus Fever.—Gottstein marshalls a great body of statistics, old and more recent, on this subject, which should be incidentally of service in showing that the deadliness of the disease is greatly exaggerated in the popular and even medical mind. Only in exceptional cases has the death rate ever reached 50 per cent., and here the material may have been too small for a fair computation, or the milder cases not included. Age incidence is also a factor of great importance, for the death rate, very small in children, increases progressively with age. In the elderly (over 50) it is comparable with that of lobar pneumonia, while in childhood it may be compared in this respect with measles. In troops, at least when not besieged, or exhausted by hardships, the mortality should be in proportion to the age and has been as low as 14 per cent. As a class, however, army mortalities have sometimes been very high, and are ranked as higher than civil mortalities. The death rate in civil hospitals is somewhat below 20. General mortalities involving entire countries have varied greatly—from 6 per cent. (!) to 22.5 per cent.

In attempts to strike an average figure Griesinger reached 15 per cent., while years later Prinz placed it at 10 per cent.

Having made an effort to obtain figures which could be utilized in life insurance calculations, Gottstein admits that these are not worth the time devoted to them. Numbers have been grouped and compared without the least attempt at standardization. With precisely the same material different reporters have sometimes reached quite different conclusions. Virchow's observations on an epidemic in upper Silesia bear out the truth of this argument to a discouraging degree. Worse discord could hardly be imagined. Gottstein nowhere alludes to the great difference between early and late mortalities in the same epidemic, a fact which has been noted in the present European war. The initial mortality has at times been far greater than that of any of the other types, but this does not enter into the statistics.

As matters now stand any man may select his own mortality. We can only discuss from this viewpoint the individual himself. His chance of escaping typhus and of surviving it is in direct proportion to his years, constitution, and social position. —*Blätter für Vertrauensärzte der Lebensversicherung*, September-October, 1915.

Book Reviews.

URGENT SURGERY. By FÉLIX LEJARS, Professor Agrégé à la Faculté de Médecine de Paris; Chirurgien de l'Hôpital Saint-Antoine; Membre de la Société de Chirurgie. Translated from the Seventh French Edition by WILLIAM S. DICKIE, F.R.C.S., Surgeon North Riding Infirmary, Middlesbrough; Consulting Surgeon Eston Hospital, and ERNEST WARD, M.A., M.D., F.R.C.S. Third English impression with 20 full-page plates and 1086 illustrations, of which 729 are drawn by Dr. E. DALEINE and A. LEUBA, and 198 are from original photographs. Volume II, The GENITO-URINARY ORGANS, The RECTUM and ANUS, The STRANGULATED HERNIAS, The EXTREMITIES. Price per volume, cloth, \$7.00 net; half morocco, \$8.00 net. New York: William Wood & Co., 1915.

A REVIEW of the first volume of this edition, covering the emergency surgery of the head, neck, spine, chest, and abdomen, appeared in the *MEDICAL RECORD* of May 22, 1915. This second volume covers the emergency surgery of the genito-urinary organs, the rectum and anus, the strangulated herniæ, and the extremities. One who, like the present reviewer, has critically read many books on surgery and waded through the mazes of circumlocution and inconsequential detail so often encountered, cannot fail to be impressed with the clearness and conciseness of diction in Lejars' "Urgent Surgery" and appreciate to the full the author's genius in getting at the crux of the matter and driving home the important points in diagnosis and treatment in the fewest possible words. Diagnosis, differential diagnosis, treatment, often under various assumed conditions and in the presence of various complications, the technique of one or several methods of manipulative or operative treatment—all those and more are covered systematically and well, while the frequent citation of illustrative cases serves to make the subject still more clear and emphasize salient features.

It is hard to single out particular subjects as especially worthy of mention, for there is not an unimportant or uninteresting page in the book. The indications and technique of posterior colpotomy; the handling of urinary extravasation and urinary abscess, traumatic rupture of the urethra, foreign bodies in the urethra and rectum; the various methods employed in the treatment of anorectal imperforation; the proper handling of irreducible or strangulated rectal prolapse, of ischio-rectal abscesses, and of an almost endless variety of hernial conditions of urgency; the diagnosis and proper methods of reduction of the various dislocations; the diagnosis and treatment of fractures; the treatment of wounds and ruptures of vessels and tendons—these are but a few of the many subjects of special interest not only to the surgical specialist, but also to the general practitioner, who is often thrown upon his own resources for emergency treatment. The treatment suggested is conservative where conservatism is for the best interests of the patient; but, as is frequently emphasized, delay and half-way measures are not always conservative and where a situation demands radical or even bold surgery such measures are advised.

While this volume covers the emergency surgery of the regions enumerated in the transcription of the title page, the two volumes together constitute the most comprehensive and practical exposition of this branch of surgery in any language. This fact is so well recognized that the work has been translated into at least seven other languages and has long been regarded as a classic. With this revision the work is brought up to date in every way, and with the truly remarkable series of illustrations and plates can hardly fail of securing still greater popularity; for we feel that the man who is entirely conversant with its teachings and who possesses the requisite mechanical skill should be fully prepared to meet any surgical emergency.

DISEASES OF THE SKIN. By HENRY H. HAZEN, M.D., A.B., Professor of Dermatology in the Medical Department of Georgetown University; Professor of Dermatology in the Medical Department of Howard University. St. Louis: C. V. Mosby Company, 1915.

THE author has attempted to write a book which, on the one hand is not so voluminous that it is hard for the inexperienced general reader to grasp the essential facts, and on the other hand is not merely an exaggerated quiz compend. He has omitted a discussion of the very rare diseases as a rule, but has described the common ones quite fully and has paid especial at-

tention to the histological pathology of many of the common dermatoses. Illustrations are very numerous and consist chiefly of photographs of cases seen in the author's clinic. Many of the illustrations are microphotographs which show pathological conditions. The work is exceedingly well written and will prove a valuable aid to the general practitioner.

VIEWS ON SOME SOCIAL SUBJECTS. By SIR DYCE DUCKWORTH, Bt., M.D., LL.D.; Fellow and Treasurer of the Royal College of Physicians; Consulting Physician to St. Bartholomew's Hospital. London: George Allen & Unwin, Ltd.; New York: The Macmillan Company, 1915.

AT a time when the cultural aspects and dignity of medical science are somewhat dimmed by the growth of speculation, the commercialization of medical practice, and the tendency to advocate a universal system of state medicine, it is refreshing to turn the pages of this book and see the portrayal of those ideals which have always shed luster upon the medical profession. The distinguished author of this volume has had the rare fortune of a long and active professional life during a period when medicine has undergone a phenomenal growth and a no less phenomenal revolution in its methods and in its attitude to the public at large. In this volume he brings together a series of addresses delivered on various occasions. Some of these deal with the cultural phases of medicine; others with important topics in personal hygiene; others with problems of legislation, and still others with certain popular fads and fallacies pertaining to the treatment of disease. All of these provide interesting reading and food for thought. One may mention particularly the three opening addresses on "Knowledge and Wisdom in Medicine," "Reverence and Hopefulness in Medicine," and "The Dignity of Medicine," and the addresses on "The Modern Attitude of the Sick Towards the Physician," "The Ministry of Healing," and "Science and Christian Faith." The author speaks "of the dignity of medicine as evidenced by its beneficent work as a great social power in any community, and as spreading everywhere a wholesome influence. This is the particular dignity which appears to have declined in recent years, and largely ceased to inspire the respect which is due to it. It rests with us to recover and reconstitute this dignity." This is a worthy ideal for every practitioner.

THE CENTURY OF COLUMBUS. By JAMES J. WALSH, K.C.St.G., M.D., Ph.D., LL.D., Litt. D. (Georgetown), Sc.D. (Notre Dame), Professor of Physiological Psychology at the Cathedral College; Life Member of the New York Historical Society, Member of the New York Academy of Medicine, of the German and French Societies of the History of Medicine, of the Italian Society for the History of the Natural and the Medical Sciences, of the St. Louis Medical History Club, the New Orleans Parish Medical Society, A.M.A., A.A.A.S., etc. With Eighty-Six Illustrations. Price, \$3.50. New York: Catholic Summer School Press, 1914.

READERS of the previous volumes written by Dr. Walsh will know what to expect in the present work. It is based on material originally used as lectures delivered before gatherings of the Knights of Columbus. The work is divided into "The Book of the Arts," "The Book of the Deeds," and "The Book of the Words," thus reviewing the chief fields of achievement in the period covered by the Century of Columbus. The book is very readable and is enriched by many illustrations, which add to its value. The author has naturally made "selections" from the material at his command, and some of the omissions are as eloquent as anything contained on the printed pages. Sometimes his statements are extremely difficult to reconcile with the usually accepted state of affairs. In the chapter on Medicine it would appear that in the Century of Columbus the status of medical science was on a par with that existing at the present day. The circulation of the blood, occupational diseases, cretinism and goiter, hydrotherapy, balneotherapy, hemophilia, hygiene and sanitation, transfusion of blood, cesarean section, anesthesia, pure food laws, and health boards are only some of the items which were well known to the people of the fifteenth and sixteenth centuries. Indeed, they seem to have been acquainted with almost everything in modern medicine with the possible exception of turtle serum and twilight sleep.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 24, 1916.

THE PRESIDENT, DR. FREDERIC E. SONDERN, IN THE CHAIR.

Address of the Retiring President.—Dr. HOWARD LILIENTHAL made a brief address in which he expressed his appreciation of the work done by the officers and committees of the Society which had made the past year a successful one. He thanked more particularly the Committee on Membership and the Committee on Legislation, and reminded the Society that although the battles of the Legislation Committee had resulted in victory for the present they would have to be fought over and over again. Dr. Lilienthal also commended the indefatigable work of the Counsel for the Society. In closing he paid a tribute to the memory of Dr. Edward Peck and Dr. John H. Huddleston, both of whom had died at their posts in the service of the Society.

Inaugural Address of the President.—Dr. FREDERIC E. SONDERN said that he appreciated fully the honor and wished to thank the Society in electing him the presiding officer for the year. He assumed the responsibility and he was certain of their undivided support in the favor of justice, and in the condemnation of injustice. He asked what better topic could he select for his inaugural address than "Our Society." Of its growth, of the various interests represented by its membership, and of its democracy in the broad sense, they were all aware. In their search for greater efficiency, they must primarily develop and exercise self-control. The need of weighing their words and controlling their feelings became greater as the Society increased in size and importance, and its problems became more personal and intricate; for they acted not as individuals but as members of a body politic. If they made up their minds deliberately and carefully, the result was good; but if they acted hastily or passionately it was very bad. The ill-considered speech of one member might arouse others to unjust prejudice and intemperate action. One man might state a selfish desire as if it were a fact. A second man accepted it as a fact, and made it the ground for passionate expressions of hate and resentment. Still other men, who had not looked into the facts at all, were caught in this common flame of resentment, and hurried into precipitate action, which did harm to themselves and injustice to others. Such intemperance of speech or written word, while bearing actual weight only in direct ratio to the recognized worth of the individual, was destructive in principle, and justified the condemnation of thinking men in that it lowered the standard. It was their duty as members of this Society representing a respected profession, to foster constructive policies and not destructive ones, and to act at all times in accordance with the dignity they as a class desired and deserved. There had been recently some agitation in the city concerning the economics of medicine. He reminded them of the elaborate investigation of the so-called dispensary abuse. That hospitals and out-patient clinics treated gratuitously patients who could afford a physician's fee was a well known fact. Doubtless the tuberculosis, venereal, whooping-cough, and eye-glass clinics of the Department of Health did the same. While investigations had demonstrated the fact beyond doubt, the cause probably lay with the physicians as a class, and the remedy was still sought. They had all heard more or less concerning the contemplated legislation on Compulsory Health Insurance. The opportunity was offered them to confer with the framers of the proposed law. Here was an occasion for constructive work which merited their closest attention and their keenest sagacity. It was possible that the law would apply to over one-half of the population, and for this reason it was of the greatest importance that they give it serious attention now while it was in the making; it doubtless had a far greater economic weight than any law or custom affecting the physician in force in their country at the present time. Preparedness in this instance was better than watchful waiting. Calamity howling on a grand scale afterward would not bring complete relief from possibly unreasonable measures, the enactment of which could

be prevented by proper efficient investigation and alteration now.

Military Preparedness from the Medical Standpoint.—LIEUT. COL. E. L. MUNSON, Medical Corps U. S. Army, made the introductory address, which he prefaced by saying that the officers of the United States Army were not supposed at the present time to express personal opinions on the subject of war and military preparedness and that he would confine his remarks to the work of the medical corps of an army in general and to medical preparedness for campaigns in general. The efficiency of a medical service depended on the work done in advance of actual fighting. An army medical department was not an independent scheme but was subservient to the general plans of the army, and whether these plans worked out to victory or defeat depended largely on the efficiency of the medical corps. The medical officer of the army was not engaged in curing disease but in looking after sanitary conditions in advance of a campaign and in bringing together the various relief agencies so that the sick and wounded could be properly cared for. The sanitary plans formed a part of the general plan of the campaign. When the tactical plans had been made they should be submitted to the medical officer who should go over them carefully and see what sanitary plans could be worked out. In doing this nothing must be left to chance. Every possible detail must be reduced to exactness, and every possible precaution taken to avoid illness and save life. Every source of wastage must be sought out and every tactical contingency prepared for. As soon as tentative sanitary plans had been prepared, they must be submitted to the officer having charge of the tactical plans, and where the tactical plans could be changed to secure better sanitary conditions this was done. After revision these tactical plans were again submitted to the medical corps and it set to work to make a more definite study of every detail. It was quite necessary to know what interference there would be with the efficiency of the fighting force from transmissible disease and in this respect very shrewd estimates could be made. In getting this information the medical officer consulted all available statistics with reference to the health of the locality in question and the incidence of transmissible diseases. He consulted the narratives of travelers to learn what he could of the nature of the diseases most prevalent. He sent medical observers over the ground to learn what they could before the locality was occupied by the army. If the area had been occupied at any previous time by an army, a study was made of the medical history of former campaigns as from this much might be learned as to what might be expected in the future. Attention was given to clothing, climate, and a study of the race living in the locality under consideration. All the climatic conditions, temperature, humidity, rainfall, character of the soil, ground waters, terrain, latitude, altitude, and seasonal influences were taken into consideration in the medical plan for the campaign. Based upon these all the sanitary details for the military community were worked out. Maps of the plans were prepared, all sanitary information collected, and arrangements made for distributing sanitary orders. Estimates were made showing how many men might be counted on as in fighting condition and what provisions might have to be made for reinforcements to make up for those not ready for duty. Arrangements had also to be perfected for caring for the wounded near the line of battle and for transportation facilities for removing the wounded to base hospitals. The medical officer must also be informed of the means of transportation in the vicinity that could be depended upon and of all existing hospitals, and also with reference to all lines of transportation carrying the men home and their medical equipment. A study must be made of the requirements in the way of drugs and dressings and of the amount that would probably be needed. Proper provision must be made for a sufficient sanitary personnel based on the amount of work that it was expected would have to be done. All these things should be prepared in advance of actual hostilities and should be adequate to meet all exigencies, and to this end a sufficient appropriation should be made that should not be governed by business or political interests.

Dr. KARL CONNELL, recently in France for the Columbia University Unit, and Observer in Germany and Austro-Hungary, spoke for the civilian. He said that modern war was not merely the clash of swords at the battle front. It was an intense economic struggle that involved every phase of natural activity. Those of them

who had seen the present European war at close range were profoundly impressed by the complex organization which kept the soldier on the firing line, more by the organization than by the work of the firing line itself. A vital unit of this organization behind the soldier was the sanitary department. Dr. Connell said that he had an opportunity last winter to observe certain phases of the surgery and sanitary organization in France, Germany, and Austro-Hungary. He was deeply impressed by what martial efficiency meant, by the slow preliminary preparation necessary for efficiency, by the intensive organization, the mental and physical preparedness in time of peace which alone made for success in time of war. As against infection by disease, so against war, preparedness was the one vital lesson they brought home. He said that his remarks on organization and efficiency might seem to favor a certain belligerent. They were made, however, in a spirit of faithful record of conditions as he saw them. Those of them who had seen the barbarous inhumanity of inefficiency in war became indignant at needless sacrifice, and fanatical attitude toward the soft, pulpy spirit manifested by a certain element in this country, a spirit far removed from the Spartan devotion and willing sacrifice which alone founded and could maintain their nation. It became a duty to impress upon the members of the Medical Society of the County of New York the medical needs in war and sow the seed that would bring this country to physical, social, and military fitness. It hardly needed recapitulation that our own wars had been sanitary disasters. In the Civil War it took over two years to approach efficiency. Through the entire course of the Spanish-American war we paid a fearful toll in needless death and crippling for sanitary unpreparedness. To-day we were scarcely better prepared; although the medical corps of the regular army was highly efficient yet it was scarcely half the strength required for our small army on a peace basis. Our future depended on the training by a small professional army, and the larger army of citizen soldiery, men trained as in Europe, alike a national asset in peace and in war. Correlated with this we must become medically efficient by organizing our civilian surgeons. The professional military surgeon did not do the surgery of the war. He was primarily an officer of sanitary administration. His duty was to keep the health of the troops, getting supplies, and ridding the fighting zone of sick and wounded. Such sanitary duty was essential. It was learned only by long service with troops in the field. Men for such service, America must train; but for the actual surgery of war, the accidents of peace had already trained a great body of civilians. With them, as in Europe, the actual surgery of war would be done by the civilian surgeons, working in the base hospitals of the rear. Dr. Connell then spoke of the surgery of the war which did not differ from the surgery of peace. No day of usefulness for national betterment was lost during the convalescent stage. The wounded were given instructions in arithmetic, geography, conversational French, German grammar, practical illustrations in the pruning and grafting of trees and vines, the dividing of potatoes for planting, etc. The head wounds from the German West front were largely gathered in Cologne under Professor Preysing. The mandible cases were concentrated at Düsseldorf under Professor Bruhn. In this clinic reconstructive surgery, after the terrible face injuries, reached its highest development under a surgeon already trained in the accident service of the Essen Iron Works. In retrospection of all the marvels of intricate organization, the most impressive feature was the economic results. The acute cases were less severe by virtue of prompt treatment. The chronic cases were not backing up, like logs in a jam, to be cleared out after the war; each case was moving smoothly to its final cure with the system and precision of peace. It was the economic, humanitarian, impersonal triumph of organization. The medical corps of our regular army was numerically entirely inadequate and should be strengthened. He said he wished to speak for the civilian surgeon for whom no efficient organization existed. The reserve medical corps was loose, disjointed, and uncontrolled. They should organize through this country, around each great hospital group and medical universities, a base hospital unit, each with full personnel of surgeon, internist, orthopedist, x-ray operator, nursing staff, administrative and clerical staff, druggist, mechanic, carpenter, cooks, etc., all ready to establish a hospital in a warehouse, a summer hotel, a village, or a factory at a day's notice. Units of this

kind were the only efficient ones the United States had sent abroad. In closing Dr. Connell said that to-night was part of the square issue, *preparedness*. If conflict came should we by lack of organization again condemn our wounded to the horrors of neglect as in previous wars? Should we maim and slaughter them by infections more deadly than the enemies' bullet? Should we strain their natural resources in life, in money, and in pension roll, or should we be prepared?

Major S. H. WADHAMS, Medical Corps U. S. Army, said that his remarks were not to be taken as an expression of personal opinion, but simply as a statement of the present position of the country in respect to medical preparedness. It was evident that the present medical organization of the army which was scarcely adequate for times of peace would impose a tremendous burden on the civil profession in the event of war. The result of medical unpreparedness had been amply demonstrated in the past and unless we learned the lessons of former wars the same inefficient provisions for protecting the lives and health of the men from the onslaughts of disease would result in untold suffering, loss of life, and increase in the pension roll. The medical resources in case of war were about 444 medical officers in the United States Army, about 850 in the National Guard, and about 1500 in the National Reserve Corps. As some of these were counted twice, the actual number of available medical officers was less than 2500. Again the position of the medical officer in the army in time of peace was rather peculiar; he was more of a general practitioner of medicine taking care of the officers, their families, and their servants. He had to be a specialist in otology, in obstetrics, in pediatrics. In time of war the duties of a medical officer required quite a different sort of training from that needed for the general practice of medicine. The medical officer himself might be partially responsible for the impression that if one put an army uniform on a medical man one made of that man a medical officer. If a man was merely a doctor he was a very poor medical officer; indeed it was almost inconceivable that a man should be a practitioner and also a competent medical officer. To be thoroughly efficient the medical man must have special training as a medical officer. This being true it was evident that the Act of April 23, 1908, which provided that members of the Medical Reserve Corps give their services only in times of emergency is woefully inadequate. The members of the Reserve Corps could be assembled one week in two years on invitation to which they might or might not respond according to their inclinations. When the medical men of the Reserve Corps were invited to meet they had to pay their own expenses. As to the number of medical officers that were required, the army numbered 2,000,000 and there were only 20,000 medical officers, or 1 per cent., which was not enough. It must be remembered that in time of war we must have medical officers at the front, in the lines of communication to the base hospitals, in the base hospitals, and from the base hospitals to the home territory. For duty at the front a man must be a trained organizer and a sanitarian; his first and most important duty was to keep the men well. He must be able to separate the trivial cases from those needing special treatment. He must be able to tell when a man needed only temporary care and when he should be transported for hospital care and he must be expert in keeping records. None of these duties required a high order of medical or surgical skill but they did require administrative ability. A plan that might be adopted would call for 1 per cent. of medical officers, one-half of these for the front and one-half for the base hospitals. From the time of leaving the base hospital the men would have to be cared for by the Medical Reserve Corps and the civil practitioner. An army might get along with a reduction in its cavalry or in its artillery, but if it lacked sanitation it meant that there would be a great unnecessary loss of life from disease and a large number of pensioners. The experience of the Spanish-American war should teach the necessity of medical preparedness and that we could not depend on a voluntary service that could be accepted or rejected at will. We must be prepared before the emergency arose. Members of the medical profession were always ready to do their part and, if properly prepared, would do their part in winning victory for the country in time of war and in serving humanity in time of peace.

Lieut. Col. WILLIAM S. TERRIBERRY, Chief Surgeon Division N. G. N. Y., read this paper. He said we must assume a basis of some argument in a discussion

such as this and he would, therefore, assume for the sake of argument that there was a demand throughout the United States for an adequate military and naval preparedness and that this demand had been made by a majority of the people of the country. Following this assumption, the question now arose as to what method of organization and armament was to be carried out. There were three schemes of organization which were now prominently before the public, (1) the scheme proposed by the Staff of the Army; (2) the so-called Continental Army Organization, the plan of the Administration; and (3) the Federalization of the Organized Militia. The General Staff proposed a greatly increased regular army, a short term of enlistment, and a reserve. It provided for a continuation of the soldier's training in the reserve during a period of years and finally enrollment in a reserve without further training. This plan perpetuated a system of highly trained, mercenary, professional armies, a military organization hopelessly out of date. Our army consisted of a select few who volunteered to make the career of arms their chosen profession. Mobilization of the regular army for war would necessitate an infusion of 60 per cent. of green men and probably 40 per cent. of untrained officers and this meant that our present army would not be able to take the field for at least three months after mobilization. The Administration's plan for a peace time volunteer army provided for the enrollment of a force of 400,000 men in annual quotas of 133,000. The force was raised by authority of Congress and was to be under the direct orders of the President in both peace and war. It was to be trained by the regular army, armed, equipped, and paid by the Federal Government. The army was not to be assembled, except for short periods each year. Such a plan assumed that there were 400,000 men of military age and fitness, willing to give up their usual occupations entirely for a month for the compensation of soldiers in the regular army. Even if there were this number of volunteers how could we expect them to become soldiers by this kind and duration of training? A soldier was made by the habit of discipline, the implicit obedience to orders, and by the morale which came from constant contact with disciplined men. The Continental Army left these all-important objects unattainable. The National Guard system was worth perpetuating and developing only upon condition that it could be standardized to a common high level, and that it could be made available to the Federal Government for use at any time, for any purpose, and as long as it was needed. This could be done only by radical changes in the law which probably could be easily made, and of all plans of military preparedness, the regulation of the Organized Militia offered the best prospect of development into a National Army of the 20th Century Model. Whatever the form of organization, a great part would be played by the medical profession. It was not too much to say that the success or failure of future wars might depend upon the care that was given to the organization of this department. The smallest proportion of medical officers that would be needed for service with troops actually in the field was 1 per cent., and probably more would be needed. These men would have to be medical officers and not civilian doctors, improvised into officers. To train these men took years of instruction and practice. Their duties were largely military, based of course on a thorough knowledge of their own profession. The question was how were they to get these men. Would they volunteer in time of peace and make the necessary sacrifice of time and money? In the opinion of the writer they would not. Short periods of annual maneuvers would not go far toward producing competent medical officers. Their specialty must be taught by continuous contact with the troops supplemented by field work with large bodies of troops under service conditions. In addition to these medical officers a vast number of practitioners would be needed for service at the rear. Even this class would need to be organized in time of peace, in order that they might be immediately available upon the onset of war. As yet no steps had been taken to authorize any such organization. The views at present on this subject were hazy, inchoate, unformed. The best organizations seemed to be a civilian base hospital unit, complete with consultants, operating surgeons, assistant surgeons, specialists, laboratory men, and a nursing force. This unit should be organized and its personnel kept up during peace to a full war strength. For the members of this unit military instruction was necessary. The unit would differ in no way from a

modern civil hospital. The military knowledge necessary to the conduct of this hospital would be supplied by the commanding officer of the hospital who must be a medical officer of rank and with much military experience. It must be recognized that the public of this country knew well what constituted a good medical service, and would demand that kind of treatment for the army's sick and wounded. If the government wished the support of the people of this nation it must see to it that the sick and wounded got the best possible care. Victory was obtained by having the greatest numbers available for service where they were needed and at the time when they were needed. This meant that every wounded man must be returned to the ranks at the earliest possible moment for duty. Again this implied the best surgical treatment all the way from the spot where the wounded man was hurt to the place where he completed his convalescence. It also implied that the recovered soldier never was out of the hands of military authority, no sick furloughs, and no political favors to cover malingering. In conclusion the writer modestly expressed the opinion that no adequate method of national defense would arise from the present agitation. The nation had never been actually tested in war and it would take a real war with an overwhelming defeat to convince us that a national army based upon universal service in time of peace was our only safety.

Major EDMUND P. FOWLER, Surgeon 7th Regiment Infantry, N. G. N. Y., read this paper in which he stated that the regimental officer was responsible for the sanitary condition of the regiment. A regular monthly examination was made of every soldier and the records kept. The sanitary detachment was responsible for the sanitary operation of the kitchen, the care of urinals, the collection and disposal of waste, and for the sanitary condition of the public washing and bathing places. Since the very ill were an encumbrance to an army, such men were transferred to the surgical division and provision had to be made for their safe and comfortable transference. The regimental sanitary detachment had to accompany the troops to the front in time of battle and establish a first-aid station near the firing line. Such a station must be prepared to give first aid and to direct wounded soldiers to the rear, or when they were too badly wounded to walk to assist them to the rear; in many instances this aid had to be given after dark. There were many important problems in connection with the various branches of the work of the sanitary detachment which made special training necessary. The medical officer must not only be a trained doctor but a trained soldier. There were two ways to train men for this duty. These were either in the National Guard with the troops or with the Reserves and physicians should avail themselves of these methods since in the event of war the medical profession must not be found wanting. Conditions abroad had shown the results of medical unpreparedness and if in the future they were to avoid such results, training in the medical service required to meet the demands of war must be universal.

Dr. HENRY C. COE said he wished to speak for the Medical Reserve Corps of the Army. There had been several disparaging remarks with reference to the Medical Reserve Corps. In 1908, when Congress provided for a General Medical Reserve Corps, such a corps was regarded as a joke and remained so for a long time. The man who accepted a place in the corps assumed no great obligations. Recently, however, there was a changed condition of affairs in the corps. Five or six years ago Dr. Coe went to Gettysburg with the troops to learn what he could with reference to the possibilities for usefulness of the Medical Reserve Corps. He then made up his mind that he would try to galvanize this dead body into life. The effort had been attended with great success in this State. The Medical Reserve Corps in New York State numbered 230 to-day, and there was not a man in the organization who would not pledge himself to be ready to serve when and where he was wanted. They wanted young, active men. He had asked a young man to join who had replied that he did not want to go to Mexico. They did not want that kind of men, but men who were patriotic and ready to serve their country. The medical man should be under the same necessity of giving his services to the State as of giving them to humanity. He willingly gave his services to humanity, why not to the State and to the flag?

Dr. SAMUEL J. MELTZER expressed his appreciation of Dr. Connell's paper and the decided way in which he

had called a spade a spade. He had also told them what the men in the United States could do. Their hospitals and universities could be used; the hospital and university units sent abroad gave better service than the foreign countries had been able to provide. There were some statements made with which he could not quite agree, and one of these was with reference to the question of preparedness of the Army Medical Corps; it was astonishing what we had accomplished in the last sixteen or eighteen years. We had learned the cost of not having an efficient medical service in the Spanish-American war and that very able Surgeon-General, Dr. Sternberg, had laid the foundation for an efficient army medical corps in the Philippines and in Cuba, and they had accomplished a great deal in many trying circumstances. Dr. Sternberg had demonstrated that a medical man could be patriotic and would give his utmost service to his country, and that this service was at the same time not in contradiction to his service to humanity.

Dr. EMIL HEUEL said we had heard much of preparedness from the technical standpoint of the army surgeon; we had listened to an exposition of the situation from the side of the State, and he would like to say a few words for the layman. When the State accepted the services of a soldier, it gave him a uniform and a certain financial compensation, while the man in the Medical Reserve Corps had to furnish his own equipment, and give a great deal of time to preparation for the service, for which he received nothing, excepting at such a time as he might be in active service, when he was allowed \$5 a day. The Federal Government should recognize the burden that preparation for military service imposed on the civil practitioner and give him fair treatment.

Demonstration of the Efficiency of Moving Pictures in Surgical Teaching.—Dr. J. BENTLEY SQUIER made this presentation. Before giving the demonstration he said that this method of teaching operative surgery had the advantage that operators all over the world might be familiar with the work of other operators, and that the work of any man could thus be made accessible to all. Dr. Squier said that when he had finished his demonstration he wished to have an expression of opinion as to whether it was not possible to see more of the technique of an operation by means of the moving pictures than in the amphitheater. The moving picture of the operative procedure had the additional advantage that if there was any part of the operation which the student did not understand he could stop the reel and repeat. The moving picture demonstration showed the various steps in a suprapubic cystotomy, an operation for the removal of a stone from the pelvic portion of the ureter, and an operation for congenital inguinal hernia with a certain degree of undescended testicle. In ureteral work the patient was put in the extreme Trendelenburg position and the operator learned when operating for a moving picture to keep his hands from obscuring the operative field. It might also be observed that only the operative field was thrown on the screen, never the face of the operator, thus eliminating as far as possible sensationalism or undesirable publicity for the operator. The production of a moving picture of an operation was rather expensive at present; an operation lasting twenty minutes cost about \$175 to \$200, but the educational value of such a film was untold. The pictures showed all the steps in the operative technique in the operations above mentioned, and since in the operation for enucleation of the prostate the actual work of enucleation could not be seen by the student, models showing the technique of enucleation were introduced into the picture by which every part of the operation could be demonstrated.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held January 13, 1916.

Dr. ROYAL S. HAINES IN THE CHAIR.

THIS meeting was devoted to the progress in pediatrics during 1915.

Hookworm Disease in a Boy of Eleven and Girl of Ten Years. Microscopical Examination. Dr. SARA WELT-KAKELS presented these children who had contracted the disease in the West Indies. She related the histories showing the typical picture of hookworm disease, and gave a microscopical demonstration of the parasites.

Cutaneous Reactions in Cases of Food Idiosyncrasy.—

Dr. OSCAR M. SCHLOSS read this paper. He said he had had an opportunity to study a number of cases of food idiosyncrasy and that there were a few observations concerning the significance and limitations of such tests which seemed of sufficient importance to warrant a brief summary. The test with food substances might be applied by cutaneous inoculation or by means of an intracutaneous injection. The former was the easier method, and for this test food substances might be used which were too irritating to be injected into the skin. The intradermal method, however, was the more sensitive and at times would prove positive when the cutaneous test was negative. A positive reaction might occur in one of two distinct forms. The most common reaction, especially with the cutaneous test, was the occurrence of an urticarial lesion. This appeared almost immediately after the injection, and disappeared within 15 to 20 minutes. With this form of reaction itching was common but not constant. The second type was analogous to the tuberculin reaction, was inflammatory in character, appeared only at the end of a few hours, and was usually most marked after 12 to 24 hours. This form of reaction was relatively more common after the intracutaneous test but was much less frequent than the urticarial type, at least in the cases with which the writer was familiar. With regard to the materials used for the test, foods that were rich in soluble protein might be used unaltered or simply diluted with salines. It was always preferable, however, to use the proteins in a comparatively pure state as in this form they were better adapted for intracutaneous tests. Hitherto the difficulty of their preparation had been an obstacle to their use, but recently the writer had obtained some preparations from Dr. Harris, who had had a long experience in such with Osborne and Mendel. When a positive reaction was obtained in a given case, the question naturally arose as to what was its exact significance. Practically without exception such a reaction was indicative of an idiosyncrasy to this particular food substance. Dr. Schloss stated that he had never seen a clearly positive reaction to a food protein when such food did not cause a toxic disturbance when ingested. The opposite phase of the question was not so satisfactory, namely, "Does a negative skin reaction exclude the possibility of food idiosyncrasy?" Unfortunately such was not true. There were many cases of food disturbances in which the history was perfectly definite, and yet all the tests were uniformly negative. As a rule a positive reaction might be expected in the patients who reacted to the toxic foods by the development of skin lesions. In the cases with gastroenteric disturbances only, the cutaneous tests were often negative. Another influence mitigating the value of the cutaneous test was the occurrence of temporary desensitization. In three cases of egg idiosyncrasy he had studied this phenomena in detail. In all instances occurrence of food intoxication was followed by a temporary immunity with disappearance of the cutaneous reaction. Although the application of the cutaneous reaction to foods to dietetic problems had considerable limitations, yet in some instances such tests were of distinct value and might serve as a therapeutic guide.

The Interpretation of the von Pirquet Reaction.—Dr. HENRY HEIMAN read this paper. He said that one of the first important diagnostic aids in tuberculosis was the discovery of Koch's tuberculin reaction but on account of certain disadvantages its application was limited. If the proper technique was observed he believed that one could safely rely upon this valuable diagnostic aid. By proper technique was meant the performance of the test in such a manner that only the epidermis was removed by a proper borer. Frequently a needle or scarifier was substituted for the borer; this at once invalidated the test owing to the opening of capillary blood vessels and the consequent rapid absorption of the tuberculin. The chief object of the tuberculin test was to produce merely a local effect by bringing the existing antibodies to the site of the test, thus causing a union of the tuberculosis antibodies and the tuberculin, the so-called lymphocytic and giant celled infiltration. Observations regarding the interpretation of this test had led to the belief that in the case of an acute tuberculous process, a very marked reaction occurred; in subacute or chronic tuberculosis a milder reaction was usually observed; in the last stages of tuberculous meningitis, or in general military tuberculosis, the reaction was usually negative. In the last two instances the system was so overwhelmed by the tuberculous process that the antibodies in the blood had become practically exhausted. An advantage of the von Pirquet

over the subcutaneous or Calmette tests was its almost absolute safety. In the children's service of Dr. Koplik at the Mount Sinai Hospital, in applying the von Pirquet test several times within two or three weeks on the same individual, in a series of 100 patients, it was found that in those in whom the reaction was positive in the first instance, it remained positive as a rule in the subsequent test. In only three of the 100 cases did this observation not hold good. Furthermore, they had noted that in the cases of tuberculous adenitis in which the von Pirquet reaction was markedly positive before operation, there was just as marked reaction after the radical removal of the tuberculous glands. This could only be explained on the theory that the sensitization of the individual had occurred or that possibly there remained some additional glandular or other tuberculous focus. Despite the positive value of the test, Dr. Heiman expressed the opinion that the negative value was of still greater importance in excluding the existence of tuberculosis, with the exception of the last stages of tuberculous meningitis and general miliary tuberculosis, both of which, however, could as a rule be diagnosed at the bedside. The von Pirquet test was of far more value than was generally conceded, and should be more universally employed than at present in cases of doubtful diagnosis in infants and children.

Progress in the Knowledge of Tuberculosis Infection—Fever the Initial Symptoms of Tuberculous Infection in Infancy.—Dr. MARK S. REUBEN presented this paper and offered the following conclusions: (1) The tuberculin reaction was a specific reaction. A positive reaction signified the presence of a tuberculous focus, either active or latent, somewhere in the body. Normal individuals could not be sensitized with tuberculin. (2) All human beings were predisposed to tuberculous infection; children of tuberculous parents were more apt to be tuberculous because they were more exposed to infection than were other children. Before they became infected infants of tuberculous parents showed the same physical development and gain in weight as did average children without tuberculous infection. The importance of separating infants from the tuberculous parents was apparent. Predisposition was easily overcome if exposure to the source of infection was avoided. (3) Fever was the first symptom of tuberculous infection in infants; the fever was low and more or less continuous with exacerbations of high temperature which was remittent; in cases which got well this fever lasted from 12 to 20 weeks. (4) The tuberculous reaction in these cases usually became positive at the onset of the fever or within a few days after the onset. (5) At the onset of the infection no physical signs were present; within the course of a few weeks these cases all developed signs in the chest, which, in those patients who got well, gradually disappeared. (6) The prognosis of tuberculosis in infancy was more favorable than was formerly supposed; 3 to 35 per cent. of these infants survived the infection. (7) From these facts one was led to the conclusion that the pathological lesions even in infancy might be localized and completely healed. (8) Fourteen per cent. of the febrile conditions in infants diagnosed as influenza gave a positive von Pirquet reaction; it was possible that many other fevers of obscure origin in infants, children, and adults, were due to a reaction of the body to tuberculous infection. (9) The tuberculin reaction should be performed in every infant who had an idiopathic fever and presented no physical signs.

Progress in the Treatment of Skin Diseases.—Dr. GEORGE M. MACKEE said that for a full appreciation of the advances made in dermatology it was necessary to broaden their conception of the subject. It was not tenable to-day to consider dermatology as consisting of diseases which were limited to the skin and which should be treated by chemical and physical agents applied externally, and the empirical use of arsenic, iron, and a few other internal remedies. Probably the greatest advance, or at least the most promising evidence of progress that was being made in dermatology, was the recognition that most of the dermatoses were intimately related to internal medicine, that the genesis was only occasionally in the skin, and that the pathology was by no means limited to the integument. They could never hope to treat skin diseases intelligently and successfully until they possessed a reliable knowledge regarding their etiology; therefore, the enormous amount of research work being done by McBride and Scorer, Rose, and many others in an attempt to associate the causative factors with the internal secretions, with gastrointestinal disturbances, focal infections, pathological

and physiological disturbances in the important viscera, anaphylaxis, etc., must be considered as bearing directly upon the therapeutics of cutaneous medicine. Many of the dermatoses were known to be but external manifestations of more or less grave internal disturbances. So far as present and future real progress in the treatment of diseases falling under the head of dermatology was concerned, they must depend upon the combined efforts of the dermatologist and the internist with the collaboration of the physiological chemist, the bacteriologist, and the pathologist.

Progress in Pediatric Surgery of the Brain.—Dr. WILLIAM SHARPE presented this paper in which he spoke particularly of cerebral spastic paralysis. He said there were four chief neurological surgical conditions found in children: (1) Cerebral tumors and cysts, hydrocephalus and spina bifida; (2) brachial birth paralysis due to an injury of the brachial plexus during a difficult labor; (3) cerebral spastic paralysis due to one of three main causes, namely, lack of development of the cerebral cortex or its pyramidal tract, a meningoencephalitis, following an infection, as scarlet fever, measles, etc.; and (4) hemorrhage, especially intracranial hemorrhage occurring at birth. It had always been believed that such hemorrhage caused a destruction of brain tissue and that where there was destruction of cortical nerve tissue there could be no regeneration, and consequently it was believed that nothing could be done to improve this condition. Attempts had been made at different times to improve this condition. Twenty-five years ago operative procedures were undertaken but the osteoplastic bone flaps were not permanently removed, and hence no permanent decompression had resulted. At that time no effort was made to distinguish between cases due to the three different causes and consequently these operations had been very disappointing, as many cases were operated upon which could not possibly be helped by any operation. In regard to his first case, Dr. Sharpe said he was called to see a child who was in status epilepticus, having had 300 convulsions during the preceding four days, and who had a condition of left spastic hemiplegia. Choked disc was present, owing probably, as he then thought, to the convulsions. A right subtemporal decompression was performed to relieve the pressure, and not only did the child make a recovery, but there was a lessened spasticity so that the child could walk with his left heel on the ground, and he began to use his left hand and arm for the first time in his life. It then occurred to him that some of the cases of cerebral spastic paralysis in the different orthopedic clinics might show signs of mild intracranial pressure and that it was most important to distinguish these cases from the ones that might be accounted for by other conditions, such as lack of development and meningoencephalitis. He examined these cases carefully with the ophthalmoscope and also measured the pressure of the cerebrospinal fluid by lumbar puncture, and when he found intracranial pressure he advised a subtemporal decompression. Up to January, 1916, he had examined 832 cases and had advised cranial decompression in 209, these cases showing an increase in cranial pressure denoting hemorrhage. He had operated upon 195 cases and had had 14 deaths. Of these deaths seven were extreme diplegias, with marked malnutrition, having difficulty in swallowing; two died from pneumonia; two from shock; two from infections, and one from enlarged thymus with a supracortical hemorrhage disclosed at autopsy. Permission to perform an autopsy had been obtained before operation in all cases. The remainder of the cases had improved both mentally and physically, with the exception of eight patients who had shown little or no improvement. In only seven cases was the hemorrhage subcortical, thereby causing a primary destruction of nerve tissue; in the other cases the high intracranial pressure from the hemorrhage upon the cortex was the cause of the spasticity. It might be said that of the entire number examined one in four showed signs of intracranial pressure. All the cases which were caused by hemorrhage gradually became mentally impaired because of the increased intracranial pressure. In this series of 209 cases due to intracranial hemorrhage all were first children, except 16; all were full term children except 5; only 33 did not have convulsions during the first week after birth. The condition of these children was not recognized because the spasticity was not observed until they were eight or nine months of age. All the children in this series showed definite signs of intracranial pressure by the blurring of the nasal margin or halves of the optic disc and the

cerebral fluid was under high pressure as measured by lumbar puncture. Moving pictures of the patients' gait and contractures were taken before and at regular intervals after operation, and the Simon-Binet tests of the mentality were similarly taken before and after the operation. The operation performed consisted in a subtemporal decompression; the dura was always opened and left open. The operation usually required less than forty-five minutes. It should be done with absolute hemostasis, as this was a point that was very essential in children of this age. It was also essential to prevent a large loss of spinal fluid, as a high rise in temperature due to circulatory disturbance of the basal ganglia might result. In some instances the temperature might rise to 106° or 107° F., and in such instances Dr. William Giles had learned that the head should be lowered to a marked degree, the child being almost stood on his head. This rise in temperature and its rapid fall following the lowering of the head showed that it was due to the loss of spinal fluid. The after-treatment of these cases was the same as the preoperative treatment. All the cases were given the routine hospital treatment for spastic paralysis, massage, active and passive, exercises, braces, etc. Of 82 children who were having convulsions before operation, 36 were not having them now; in others the convulsions were less frequent and less violent. In concluding Dr. Sharpe stated that most of these children were derelicts at the time they were operated upon, but if a diagnosis had been early, shortly after birth, and an operation performed, normal children might have resulted. Three of his cases were operated upon on the second day and two on the third day after birth, and normal children were obtained. The older the child the less improvement could be expected. While he did not advocate this procedure as a cure in the older children, it did offer children who were otherwise hopeless a chance of improvement.

Dr. DIAZ of Porto Rico described the conditions in Porto Rico before that island was occupied by the United States Army, speaking particularly of the laziness and inactivity of the native population in large part due to the prevalence of hookworm disease. He said that it had been shown that infection took place through the soles of the feet, and it was also true that it might occur through the skin of the hands as a result of working in the soil with the hands, and through the mouth by the ingestion of contaminated food. They had found treatment with thymol very effective. The method of administering it consisted in giving a capsule of four grains at six o'clock in the morning and following it by a second capsule of the same amount at eight o'clock. Then at ten o'clock a dose of sulphate of soda was administered. Efforts were now being made to teach the people the rudimentary elements of how to live, that they should wear shoes and wash their hands before eating. The speaker stated that he had seen patients who had become insane as a result of uncinariasis cured by the thymol treatment.

Dr. WILLIAM P. NORTHRUP said the papers of the evening had been interesting in many ways, but the first and last had impressed him most in speaking of progress. A great work had been done all over the country in taking these people who were anemic and derelicts as a result of hookworm disease and making them useful and self-supporting. Likewise the work of Dr. Sharpe was to be commended, since he took these children who were considered hopeless and undertook to improve their condition. If he succeeded in redeeming even one or two cases the work was quite worth while. If these cases could be recognized in the early stage and restored, this certainly was progress.

Dr. MAURICE FISHBERG said he would like to add to what Dr. Heiman had said that a distinction was always to be made between infection with tubercle bacilli and the disease due to the same virus. Now, there was hardly one who had escaped infection while comparatively few were affected with tuberculosis. All infected persons must react to tuberculin. Moreover the specificity of tuberculin had not been proven conclusively to the satisfaction of all entitled to an opinion. Indeed, tuberculin was not the only substance producing a reaction in a person infected with tuberculosis. Any foreign albumin inoculated into the skin of a person harboring tubercle bacilli produced a reaction indistinguishable from the cutaneous tuberculin reaction; other toxins, especially those of diphtheria, dysentery, cholera, etc., gave skin reactions exactly like that of von Pirquet. The fact that the von Pirquet reaction was negative during the terminal stages of tuberculosis and

also in tuberculous meningitis, whooping cough, and diphtheria, militated against its utility as a diagnostic agent in children when it was most needed. Tuberculin was not a simple definite substance, but a mixture of the toxins of the tubercle bacilli and glycerin salts, extractives, etc., contained in the medium in which the tubercle bacilli were grown. These substances without the tuberculous toxins produced the same reaction on the skin as the tuberculin. Dr. Fishberg said he was glad Dr. Reuben had followed infants reacting to tuberculin during the first few months of their lives, for several years and had found them thriving. He had reported similar cases some two years ago in the *Archives of Pediatrics*. This proved that the opinion that an infant under one year of age infected with tubercle bacilli invariably perished, was not well founded.

Dr. ABRAHAM L. GOODMAN said that he saw a great many children during the course of a year and had been struck by the large percentage that were infected by tuberculosis. Many of these infections were not recognized unless the child showed marked physical signs of the disease. They had been making it a practice at the German Hospital during the last four years to take an x-ray of the chest whether the child showed pulmonary involvement or not. They had found a large number of children suffering from enlarged mediastinal and peribronchial glands and they placed a great deal more stress on the finding of enlarged mediastinal glands as an indication of tuberculous infection than on other signs. Of the physical signs they had found the signs in Despine's triangle of most importance. These were the earliest recognizable signs of tuberculosis in infancy. Fever of indefinite origin was in most cases due to tuberculous infection. In the treatment of early tuberculous infection in the mesenteric, mediastinal, or peribronchial glands, or anywhere inside the body, they had been successful with guaiacol and arsenic in addition to the usual hygienic measures.

Dr. L. E. LAFETRA said he agreed with what had been said in reference to the relative infrequency of the von Pirquet reaction in very young infants, and that not very many young infants had active tuberculous disease. In many cases, especially in older children, it was doubtful whether the signs in the lungs were due to tuberculosis or simple bronchopneumonia. In some of these cases the x-ray was of very great assistance, but very often it did not give very much information. The general attitude toward tuberculosis in childhood should be much more hopeful than formerly, and the finding of a positive von Pirquet reaction should not be regarded as diagnostic unless one found physical signs or x-ray evidence of active lesion.

Dr. F. L. WACHENHEIM said that enlarged glands in the neck, as shown by Despine's sign and the x-ray, were not significant of tuberculosis in the presence of a negative von Pirquet reaction. In their clinic they were not getting such large percentages of positive von Pirquet reactions as some others; they were only getting 10 to 15 per cent. positive reactions. One might get the von Pirquet reaction in latent or cured cases. Children giving a positive von Pirquet reaction, even though they showed no physical signs of the disease, should be closely watched. It was to be regretted that institutions did not take children giving a positive von Pirquet reaction, even though they did not show active signs of tuberculosis, since they ought to be kept under observation and given a chance to overcome the infection.

Dr. BRAINERD H. WHITEBECK said that they had been doing tenotomies, fasciotomies, and cutting the posterior nerve roots in the endeavor to ameliorate the condition of the class of patients which Dr. Sharpe had spoken of, but none of these operations had been followed with any great degree of success, and recurrence of the condition for which the operation was undertaken was frequent. In some of the cases in which Dr. Sharpe had operated there were no longer any convulsions, and the walk was progressively improving, and in some of the cases in which there was only moderate mental impairment, improvement of the mental condition had been observed. The importance of determining whether there was intracranial pressure by examination of the eye grounds, and in cases in which there seemed to be such pressure of checking it up by lumbar puncture, had been emphasized by Dr. Sharpe and he also wished to emphasize it. Another important point was with reference to the bone flap; formerly the bone flap was not removed and the children did not improve on that account as the intracranial pressure was not relieved. Dr. Sharpe had frequently found it necessary to remove a flap from the opposite side at a second operation in or-

der to entirely relieve the intracranial pressure. Dr. Whitbeck cited one case in particular which he had observed in which a child having convulsions and right hemiplegia was greatly improved by the operation of decompression as Dr. Sharpe performed it, leaving out the bone flap, after a former operation in which the bone flap had been allowed to remain had failed. In all cases the dropfoot of hemiplegias and spastics might be relieved by applying braces. In cases of spina bifida, in which all improvement which could be expected by operation on the spine had been obtained, an astragalectomy and a backward displacement of the feet should be done to make it possible for the child to walk.

Dr. HENRY HEIMAN, in answer to Dr. Fishberg's remarks as to the possibility of confusing the von Pirquet reaction with that due to proteins, said there was no occasion for such a mistake, as the protein reaction disappeared in a short time while a genuine von Pirquet reaction remained for weeks. As the diagnostic value of the tuberculin test, Dr. Heiman said he would not dream of making a positive diagnosis of tuberculosis of the lungs merely from a positive von Pirquet reaction. One could make such a positive diagnosis only when the tubercle bacilli were found in the sputum or when there was a positive von Pirquet reaction plus corroborative evidence furnished by the x-ray. Frequently those using the tuberculin to make a von Pirquet test diluted it. When the tuberculin was diluted it decomposed very rapidly, but this did not happen if it remained undiluted. In full strength tuberculin kept for a long time. With the von Pirquet test a negative reaction was of great value, just the opposite of what was true concerning the Wassermann test, in which a negative reaction meant nothing. A negative von Pirquet reaction signified that the individual failing to react had no tuberculosis unless, as mentioned, he was in the terminal stages of tuberculous meningitis or general miliary tuberculosis.

THIRTEENTH RUSH SOCIETY LECTURE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Delivered Friday, January 21, 1916.

Investigative and Scientific Phases of the Diabetic Question, with Their Probable Relations to Practical Problems of Clinical Medicine.—Dr. FREDERICK M. ALLEN of the Rockefeller Institute for Medical Research, New York, began by emphasizing the necessity of keeping in mind the distinction between glycosuria and diabetes. The one was a symptom; the other a disease. One was glucose in the urine; the other a defect in metabolism. Defining diabetes, the author recognized the increasing agreement on the part of investigators that diabetes was deficiency of the internal secretion of the pancreas. This doctrine, it was said, went back to early observations of gross changes in a few cases of clinical diabetes, finally followed by Von Mering and Minkowski's production of acute diabetes by total pancreatectomy. Sandmeyer, by means of atrophy of a pancreatic remnant, produced a type of chronic diabetes comparable to the unusual human cases due to atrophy of the pancreas. A more accurate reproduction of human diabetes was afforded by removal of most of the pancreas, leaving the remnant with its normal blood supply and duct communication with the bowel. DeRenzi and Reale first reported such an experiment in 1892. This form of diabetes was later rediscovered independently in four different places about the same time. The first in point of publication were Thiroloix and Jacob, who observed that when a sufficient portion of a dog's pancreas was removed, leaving the remainder in its normal connections with duct and blood vessels, this remnant retained its normal appearance and supplied enough pancreatic juice to maintain the animal's nutrition, yet diabetes developed and ran a gradual downward course much like the human disease. Their second important observation was that in suitably prepared animals this downward progress could be produced or hastened by over-feeding with carbohydrate. The second in point of publication was Helly, who studied only the glycogen, finding that in this form of diabetes the animals retain more or less glycogen, here resembling human diabetes. The third one in order was Allen, who dealt with various points concerning this type of diabetes, compared it with the normal and with other forms of diabetes and glycosuria, and also, thanks to the co-operation of Prof. F. B. Mallory, described for the first time the specific changes

in the islands of Langerhans in experimental diabetes. The fourth in point of publication was Homans, who discovered this form of diabetes in cats, and made the most accurate microscopic studies.

By this method human diabetes, Dr. Allen stated, could be imitated in animals in the following particulars: (1) Mode of onset, sudden or gradual; (2) the influence of diet; (3) some individual idiosyncrasies; (4) the diminished permeability of the kidney for sugar; (5) the effect of nervous influences; (6) the effect of traumatism; (7) a temporary stage during which there was glycosuria with little or no polyuria, thus resembling diabetes decipiens; (8) complications in the cachectic stages, generally not identical with the human complications, but rather an increased tendency to corresponding canine afflictions. There was no evidence that complications were due to increased blood-sugar.

The chief points of alleged difference between clinical and experimental diabetes, it was pointed out, had been the following: (1) The dextrose-nitrogen ratio, which is Lusk's figure of 3.65 in the severest human diabetes, whereas removal of the dog's entire pancreas gave only the Minkowski ratio of 2.8. Total pancreatectomy in the human subject, he said, should theoretically give a 3.65 ratio. It was well known, he observed, that phloridzin gave a 3.65 ratio in some species, and a 2.8 ratio in others; likewise the difference of species might explain the different ratios in diabetes. (2) The marked increase of metabolism in totally depancreatized dogs. To the author it seemed probable that partially depancreatized dogs with severe diabetes would not show such a great increase; it was now known that some severe human diabetics showed an increase of metabolism. (3) Anatomical changes in the diabetic pancreas. Weichselbaum had described so-called hydropic degeneration and other lesions in a series of 186 diabetic autopsies. Other investigators had not been convinced of the existence of any specific alterations in the diabetic pancreas. It was obvious that such advanced and generalized changes as were found in the pancreas in experimental diabetes were seldom if ever present in human cases, because they were too obvious to be missed. The classical work in the microscopic study of experimental diabetes was that of Homans. Using the Lane-Bensley technique, Homans proved that only the beta cells showed the exhaustion and degeneration, while the alpha cells remained intact. Homans had found some similar changes in at least a portion of the islands in human diabetes, and it would seem that the most promising prospect for the microscopic investigation lay in this direction. The functional element in human diabetes was also to be considered, which, it was said, was emphasized by the results of treatment. The rapid clinical changes possible in human diabetes seemed to the author to indicate functional rather than organic alterations in the pancreas. Back of human diabetes might be perhaps a disorder of the abdominal nerves, possibly disturbing not only the function of the pancreas, but to some extent that of other organs. Though the kidneys were generally normal microscopically in diabetes, functional changes were frequent. Further study of the pancreas obtained quickly after death and fixed and stained by the best methods was regarded as important for deciding this question, and physicians who could obtain such material would render a service by sending for study. (4) A fourth difference was that found in ketonuria or acidosis. It was an old statement that the diabetic patient died in coma and the diabetic animal in cachexia; but by stopping the over-feeding of diabetic patients coma might be less frequent. Also, under suitable conditions diabetic animals seemed to be subject to this intoxication. The present status of the theories of ketonuria or acidosis were discussed.

The fact that severe diabetics were cleared up in these respects by fasting, whereas normal persons or milder diabetics developed ketonuria on fasting, along with various other experimental and clinical observations, threw the existing theories into considerable confusion. Ketonuria and acidosis seemed to the author to be not explainable by mere lack of carbohydrate, or even by habituation or individual idiosyncrasy. The fundamental nature of the process was in doubt. Diabetes, Dr. Allen stated, might probably be defined as a specific deficiency of the power of assimilating food. The accumulation of reserves, as when the body gained weight, diminished tolerance and aggravated diabetes, whereas the reducing of the reserve stores by low diet or by exercise increased tolerance and checked diabetes. Also, one kind of food lowered the tolerance for another kind

of food, as adding carbohydrate to a diabetic diet might give rise to ketonuria and adding fat to a diabetic diet might give rise to glycosuria. The history of diabetic therapy consisted essentially in an interweaving or alternation of two principles: (1) The restriction of the sugar-yielding elements of the diet, namely, carbohydrate and protein; (2) diminution of the total caloric value of the diet. The fasting treatment was in harmony with the observed benefits of these methods in the past. This had been previously outlined and details were to be published in monograph form. The principle underlying it was a well-established one in all therapeutics—rest of a weakened function. No positive means of strengthening this function aside from rest had yet been discovered.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

CANCER OF THE STOMACH. By FRANK SMITHIES, M.D. With a Chapter on the Surgical Treatment of Gastric Cancer, by ALBERT J. OCHSNER. Octavo of 522 pages, with 106 illustrations. Published by W. B. Saunders Company, Philadelphia and London. Price, cloth, \$5.50 net; half Morocco, \$7.00 net.

PHYSICAL DIAGNOSIS. By JOHN C. DACOSTA, JR., M.D. Published by W. B. Saunders Company, Philadelphia and London. Third edition, thoroughly revised. Octavo of 589 pages, with 243 original illustrations. Price, cloth, \$3.50 net.

SEXUAL IMPOTENCE. By VICTOR G. VECKI, M.D. Published by W. B. Saunders Company; fifth edition; enlarged; 12mo. of 405 pages. Price, cloth, \$2.25 net.

THE CLINICS OF JOHN B. MURPHY, M.D. at Mercy Hospital, Chicago, December, 1915. Vol. IV, No. 6. Published bi-monthly by W. B. Saunders Company, Philadelphia and London. Price, per year, paper, \$8.00; cloth, \$12.00.

THE PRIMARY LUNG FOCUS OF TUBERCULOSIS IN CHILDREN. By DR. ANTHON GHON, translated by D. BARTY KING. Published by J. & A. Churchill, London, England. With seventy-two text illustrations, one black and one colored plate; 172 pages. Price, 10/6 net.

REPORT OF THE MEDICO-MILITARY ASPECTS OF THE EUROPEAN WAR. By Surgeon A. M. FAUNTLEROY, U. S. Navy. Published by Government Printing Office, Washington; 146 pages.

NERVOUS DISEASES. By ROBERT BING. Only authorized translation by Charles L. Allen, M.D. Published by Rebman Company, New York. 481 pages. 111 illustrations.

SURGICAL OPERATIONS WITH LOCAL ANESTHESIA. By ARTHUR E. HERTZLER, M.D. Published by The Surgery Publishing Company, New York. Second edition. 312 pages. 173 illustrations. Price, \$3.00.

THE CHILD—HIS NATURE AND NURTURE. By W. B. DRUMMOND, M.B., C.M., M.R.C.P.E. Published by E. P. Dutton & Company, New York. Enlarged and revised edition. 219 pages. Illustrations. Price, \$1.00.

THE TREATMENT OF ACUTE INFECTIOUS DISEASES. By FRANK SHERMAN MEARA, M.D., Ph.D. Published by the Macmillan Company, New York. 540 pages. Price, \$3.50.

ANNUAL REPORT—NEW YORK ASSOCIATION FOR IMPROVING THE CONDITIONS OF THE POOR. Published by Douglas C. McMurtrie. 202 pages. Illustrations.

PATHOGENIC BACTERIA AND PROTOZOA. By JOSEPH MCFARLAND, M.C., Sc.D. Published by W. B. Saunders Company, Philadelphia and London. Eighth revised edition. 807 pages. 323 illustrations. Price, \$4.00, cloth.

HARVEY'S VIEWS ON THE USE OF THE CIRCULATION OF THE BLOOD. By JOHN G. CURTIS, M.D., LL.D. Published by Columbia University Press, New York. 194 pages. Illustrations. Price, \$1.50.

BEAUTY A DUTY. By SUSANNA COCROFT. Published by Rand McNally & Company, Chicago and New York. 379 pages. Illustrations. Price, \$2.00.

AN AUTOBIOGRAPHY. By EDWARD L. TRUDEAU, M.D. Published by Lea & Febiger, Philadelphia and New York. 322 pages. Illustrations.

Therapeutic Hints.

Constipation in Children.—Agar-agar cut into very small pieces and eaten like the modern uncooked breakfast food with milk or cream and the addition of malt or sugar, makes a palatable and gentle laxative for children. The ordinary dose is a teaspoonful night and morning.—*Practical Prescribing and Treatment, Diseases of Infants and Children.*

Digitalis in Auricular Fibrillation.—Stewart and Scott employed digitalis with benefit in three cases of auricular fibrillation, the circulation as observed in the hand being noticeably improved. In one case, however, there was no response to a prolonged administration of digitalis, but on stopping the drug the circulation was improved, only to become worse again when the digitalis was again given.—*Journal of Pharmacology.*

Hemoptysis.—

℞ Pulveris ipecacuanhæ et opii, gr. xx

Aluminis, ʒi

Sacchari, ʒss

M. et div. in chart No. VI. Sig.: one powder every two hours.—Skoda.

Muscle Pains.—

℞ Tincturæ opii, ʒss

Tincturæ aconiti,

Tincturæ iodi, āā ʒij

Linimenti chloroformis, ʒiij

M. Sig.—For external use.

Weak Heart.—

℞ Tincture of strophanthus, ʒss (2.0)

Tincture of nux vomica, ʒij (8.0)

Compound spirit of ether, or anisated solution of ammonia, ʒijss (10.0)

M. et Sig.—10 to 20 drops every two hours.

—*Revista Ibero-Americana de Ciencias Médicas.*

Acute Diarrhea.—D. M. Macdonald offers the following prescription for the control of this condition in an emergency case in a child six months to one year of age:

℞ Glycerin of carbolic acid, ℥j.

Compound camphor tincture, ℥v.

Castor oil mixture, ad ʒj.

Solution of strychnine in half minim doses with brandy and normal saline solution injected subcutaneously are worthy of trial.—*Practical Prescribing and Treatment, Diseases of Infants and Children.*

Colic.—For an acute attack in children, ten to fifteen ounces of soap enema, injected slowly and steadily, will usually give prompt relief. Hot flannel fomentations to the abdomen, and a dose of castor oil if the usual cause is offending material in the bowel. If flatulence is the chief feature, give

℞ Tincture of belladonna, ℥ij.

Aromatic spirit of ammonia, ℥ij.

Bicarbonate of soda, gr. v.

Peppermint of caraway water to ʒj.

M. Sig.: Every six hours for an infant of six months.—*Practical Prescribing and Treatment, Diseases of Infants and Children.*

Dandruff.—Rub in the following ointment at night:

℞ B-Naphthol, gr. xx.

Bergamot oil, ℥x.

Vaseline, ʒj.

M. Sig.: Wash in the morning with spiritus saponis alkalinus.—*Practical Prescribing and Treatment, Diseases of Infants and Children.*

INFLUENZA.

By ALVAH H. DOTY, M.D.,

NEW YORK.

THE present epidemic of so-called influenza offers practically no new features for consideration. The conditions presented are simply a repetition of what has occurred from the earliest times, for ancient history frequently refers to this affection. There is but little doubt that the name by which it is known was proposed during the seventeenth century by Italians, who believed this disease to be due to an influence exerted by the stars, and therefore called it influenza. The French synonym, la grippe, has also been in use for centuries.

It is claimed that the specific organism of influenza was discovered by Pfeiffer in 1893, and that this disease occurs in every part of the world, at any season of the year, and is unaffected by climatic conditions. It may be stated that this belief is not universally accepted, at least not in all its details.

Whatever may be the theory regarding the origin of influenza, the name is used synonymously with "la grippe" and "cold," and relates to an infection, the local manifestation of which is an acute inflammatory condition of the respiratory tract. It will be observed that these terms have no special or scientific significance. Influenza and la grippe appear to be the more fashionable designations, and are usually applied to cases having pronounced and often urgent symptoms, while colds more commonly refer to the benign types of this affection, although no well-defined line of demarcation is recognized. Furthermore, in the treatment of these cases, bacteriological examinations are rarely made.

Whether or not influenza and colds are but different types of the same affection, and this is not unreasonable to believe, it is evident that their origin and source of infection are similar, for both are due to the presence of certain infectious organisms, and the human being is the usual means of infection, through the medium of the discharges from the mucous membrane of the respiratory tract.

Years ago it was generally believed that influenza was directly caused by certain climatic changes and sometimes by emanations from swamps, the latter theory being similar to the one originally accepted as to the cause of malaria. Although the germ origin of this affection is now accepted, the former belief as to its inciting factors should not be summarily dismissed, but rather given respectful consideration, for some of the early theories concerning the means by which infectious diseases are transmitted, although proven to be erroneous, were supported by reasonable evidence, and in a way have rendered important aid in recent discoveries regarding this subject. For instance, persons living in

close proximity to swamps are commonly affected with malaria. This disease is not caused by emanations or miasma arising from these places, as it was formerly supposed; but prevails there because swamps are the favorite breeding places of the variety of mosquito which transmits the infectious organisms of malaria. Therefore while the early investigators were wrong in their opinion as to the origin of malaria, they were right when they believed that swamps favored the propagation of this disease. The same may be said of influenza and colds, for while due to the presence of certain organisms which may be found in throats almost everywhere, it is equally true that extended outbreaks are fostered largely by climatic conditions.

The study of "carriers" offers conclusive evidence that infectious organisms may remain for an indefinite period within the body in a dormant or inactive condition without producing evidence of their presence; therefore a large part of the population is constantly acting as the hosts of these germs. This is particularly true of tuberculosis and typhoid fever, and I believe equally true of influenza. For this reason it is very important to know the exciting causes of these as well as other infectious diseases.

Whatever evidence statistics may present concerning influenza, the truth is that this affection, like other acute respiratory diseases, has its period of greatest prevalence during the cold season, particularly when abrupt changes of temperature occur associated with wet weather. Not only the medical profession but the public are practically familiar with this fact.

We have abundant proof that those who contract certain infectious diseases usually have a low resisting power, and are often enfeebled by ill health, excesses of various kinds, or a disregard of the rules of personal hygiene. It is also true that those who are in robust health do not always escape attacks from these diseases, yet it is largely the protection afforded by the resistance of healthy organs and tissues upon which we must depend for the maintenance of health, or even our existence. However, the public do not realize this, nor do they fully understand the part they should play in carrying out this exceedingly important, and what may be termed natural, preventive measure.

In generally disabled conditions of the body, local tissues, such as the exposed mucous membrane of the respiratory tract, are particularly susceptible to the activity of the infectious organisms which they may harbor. This condition is also invited by local disabling conditions of these membranes.

In dealing with influenza or colds, it is important that every reasonable means should be taken to prevent the transmission of infectious organisms from one person to another. Unfortunately, however, the medium of infection is so very widespread, including

carriers and also mild and unrecognized cases which cannot be guarded against, that the protection thus gained is very limited; besides, the public respond very indifferently to advice in this direction, particularly as it is quite sure to interfere with the ordinary business and social relations of a community.

I believe that far too little information and advice have been given the public concerning the more valuable means of prevention in this affection; that is, a healthy condition of the body, and particularly an avoidance of the more actively favoring causes of this disease, for even healthy persons are more or less susceptible to the latter. This refers to improper exposure, particularly during certain conditions of the weather. For instance, nothing contributes more directly to predisposition to acute inflammatory conditions of the respiratory tract than wet feet. It also applies to improper care of the body in other ways, for a very large per cent. of those who suffer from these affections give a clear and well-defined history of undue exposure.

It is a common practice during the cold weather for persons dressed in heavy garments to remain within doors a large part of the day in superheated apartments, where the temperature frequently reaches 80° or more, and is usually associated with defective ventilation. This is quite sure to render the body less resisting, and certainly not in a condition to withstand a difference of 40° or 50°. This is an offense to nature which carries with it its own penalty.

A careful observation of the means by which the feet and body are commonly protected will go far to explain the presence of "colds" or influenza. Nineteenths of the footgear worn by women offers no protection whatever against damp or wet streets. If wet shoes were changed immediately upon arriving at a destination, the danger from this source would be greatly diminished; however, this does not often take place, and therefore the feet remain damp or wet for a large part of the day. Even the heavier shoes worn by men offer but little more protection. Besides, so-called waterproof shoes exist chiefly in the imagination. For some reason, rubbers, although an exceedingly valuable means of protection, are not looked upon with favor in this country, whereas they should always be worn in the street during wet weather. There is a fancied objection to them on the ground that they sweat the feet. There is, however, but little annoyance in this direction if they are removed immediately upon entering the house.

Careful attention is not usually given to the ventilation of the interior of buildings during the cold season, nor is the temperature of apartments kept within proper limits; furthermore, the style of dress generally adopted for cold weather can hardly be called reasonable and logical.

It would be difficult to describe all the numerous styles and fabrics recommended and used for underwear, the value of many of them being largely theoretical. There is one material which from a scientific and practical standpoint, and particularly its suitability for all ages and sexes and various conditions of health, appears to be entitled to general approval for underwear during the cold season, and that is wool. Many wear cotton and linen underclothing throughout the year, apparently with comfort and protection, yet this does not prove that it is of equal value with wool for general use, particularly in sections of the world where abrupt climatic changes frequently occur. It should be

borne in mind that a good resisting power is often the chief support of erroneous theories concerning food and dress.

Upon the approach of winter, it is also the custom to substitute heavier outer clothing for that worn during the summer. While it is important that serviceable and protecting undergarments which lie next the skin should be provided for the cold season, particularly to guard against abrupt variation of temperature, a change in the weight and material of the outer garments is not necessary, and is often responsible for much discomfort, and sometimes for ill health.

During this time of the year, particularly in cities and large towns, persons usually remain indoors not less than twenty out of the twenty-four hours comprising the day; often where the heat of apartments, work shops, or offices equals or exceeds that of summer, but without the fresh air which is available during the latter season, for the windows are usually kept carefully closed. In these insanitary surroundings a person who is too heavily clad is not only rendered uncomfortable, but the surface of the body becomes moist and tender, and in this condition is far more susceptible to the lowered temperature when the person goes outside.

The fact is that during the cold weather heavy and uncomfortable outer garments are worn within doors in order to be protected against a brief period of outside exposure, whereas, so far as consistent, our dress should be compatible with the interior, and sufficiently heavy wraps added when we go outside; this is the function of an overcoat. It is far more reasonable, and certainly more comfortable and conducive to health, to wear outer garments of practically the same weight and texture throughout the year, except possibly in midsummer, when clothes made of very thin material, known as "tropical" weight, are indicated. Those who have adopted this logical mode of dress are fully convinced of its practical value, particularly within doors.

I believe that improper ventilation, over-heating of apartments, carelessness in dress, and direct exposure in the way of wet feet and the like, particularly when they are associated with a weakened resisting power of the body; constitute the most common predisposing factors in the propagation of influenza or "colds," and if care is taken to prevent these unfavorable conditions, it will secure greater prevention than efforts which may be made to avoid infectious organisms, although the latter should be given careful attention.

So much time has been devoted to the study of the various organisms, and the means of antagonizing them and their effect, that we have largely overlooked the importance of natural preventive measures.

Public instruction throughout the country relating to the care and prevention of influenza dwells very lightly upon these valuable means of protection, whereas special effort should be made to educate the public in this direction, for such information is of equal importance in the prevention of other diseases.

Prevalence of Smallpox.—The United States Public Health Service states that smallpox is now prevalent in Vermont, New Jersey, South Carolina, Idaho, Minnesota, Illinois, Montana, Ohio, Iowa, Michigan, Indiana, Nebraska, Pennsylvania, Louisiana, Oklahoma, and Oregon.

THE TREATMENT OF GASTRIC ULCER,
WITH ESPECIAL REFERENCE TO ITS ETIOLOGY AS AN
INFECTIVE PROCESS.

BY ALBERT F. R. ANDRESEN, M.D.
BROOKLYN, NEW YORK.

ATTENDING GASTROENTEROLOGIST, BROOKLYN HOSPITAL, BETH
SWICK HOSPITAL, AND BROOKLYN HOSPITAL DISPENSARY.

FOR the past five years or more, medical literature the world over has abounded in articles relating to gastric and duodenal ulcer. The reason for this is not hard to find. Gastric ulcer is now recognized to be of very common occurrence and, until the past year or two, knowledge regarding its etiology and therefore its rational, specific treatment has been lacking. As is always the case under such circumstances, as many different methods of treatment have been recommended as there have been articles written, internists and surgeons have been disputing each other's statistics of cure, and patients have been drifting from one practitioner to another with little improvement, and often with considerable aggravation of their disease.

It must have occurred to anyone noting the points of similarity between the attacks of typical chronic gastric ulcer and chronic recurring appendicitis, rheumatic arthritis, and other infectious conditions, that gastric ulcer must be an infective process. This has been partly borne out by the fact that, in rare instances, typical ulcers have been shown to be tuberculous or syphilitic. Until recently, however, no experimental proof of the infective theory has been at hand. During the past two years, Rosenow and his followers, with reports of the artificial production of typical gastric ulcer in animals by intravenous injections of living cultures of streptococci resembling those found in rheumatic fever (the *Streptococcus viridans*) have given us a knowledge of the etiology of gastric ulcer that should do much to establish a rational, specific therapy. They have demonstrated that the conditions formerly considered essential to the production of ulcer, namely, trauma and hypersecretion of hyperacid gastric juice, are not necessary, their experiments consisting merely of injecting the cultures into normal animals. The ulcers were usually single, small, and deep, and with a marked tendency to hemorrhage and perforation. They were not sloughs such as occur in anaphylactic shock or overwhelming bacteriemic or toxemic states. Most of them were near the pyloric end of the stomach, the fundus and duodenum being less frequently attacked. Streptococci of the kind injected were found in the affected tissues at autopsy, and occasionally other infections, such as arthritis, myositis, ascending nephritis, cholecystitis, and appendicitis, were found coexistent. The streptococci used were identical with those found in small numbers in many apparently healthy mouths, and which are usually the causative factor in oral and nasopharyngeal infections.

In the light of these and subsequent confirmatory experiments, it may with reason be concluded that gastric ulcer is an infective process. Any treatment, therefore, which fails to take cognizance of this fact, will be incomplete and inefficient. We have thus a simple explanation of the inefficiency *per se* of the various standard methods of treatment, such as the operative, von Leube, and Lennhartz treatments.

A discussion of the treatment of gastric ulcer

resolves itself naturally into two parts—the treatment of simple uncomplicated ulcer, and the treatment of the complications.

In *simple ulcer*, acute or chronic, the indications for treatment, as in any infective process, are: (1) to remove the cause of the infection; (2) to procure rest of the infected part; and (3) to aid nature in its efforts at overcoming the infection and repairing the damage done.

1. *Removal of the cause of the infection* should include the correction or alleviation of the various conditions which might have been contributing causes of the infection by having produced a locus minoris resistentiæ in the gastric mucosa, such as gastric atony, gastropnoxis, intestinal kinks and ptoses, improper habits of diet, and occupations causing continued pressure against the epigastrium.

The most important point, however, is the search for, and complete removal of septic foci in the mouth, nose, throat, and accessory sinuses, rectum, appendix, gall-bladder, pelvis, or any other part of the body. It is the neglect of this very important part of the treatment of gastric ulcer which, in the writer's opinion, accounts for the frequent recurrence of the ulcer symptoms after apparent medical or surgical cures. Most reports of cures are too optimistic, probably more than half of the cases reported as cured by either method having subsequent recurrences of which the physician or surgeon had no knowledge. Cases showing a recurrence of ulcers after apparently complete healing, either at the same point as before or at some other point in the gastroduodenal mucosa, such as the occurrence of gastric or esophageal ulcers after operation for duodenal ulcer, or vice versa, are too frequently seen to require more than mention. It is the writer's belief that no ulcers are cured unless the primary focus of infection is removed. In a recent series of 96 consecutive cases observed by the writer, infections of the teeth and gums were found in 78 or 81 per cent., infections of the nasopharynx and accessory sinuses in 15, or 15.6 per cent., and other infections, such as boils and carbuncles, fistula in ano, and pelvic infections, preceding the onset of ulcer symptoms, in 3, or 3.4 per cent. In many instances two or more of these infections were found in the same case, but only the most marked are included in the above figures. In practically all cases the *Streptococcus viridans* was isolated in pure culture. Occasionally the focus of infection has been removed before the cases apply for treatment for the ulcer, as in cases where all the teeth have been removed for pyorrhea, superficial infections, or pelvic diseases cured by surgery. In such cases a careful systematic search for secondary infective foci should, however, always be conducted.

It would seem at first glance that the *removal of the infected area*—that is, excision of the ulcer—would be a most rational procedure, but the disturbances of motility from this operation alone, and the high mortality from combined excision and gastroenterostomy, make it desirable, in uncomplicated ulcer at least, to resort to operation only after prolonged and adequate medical treatment has done no good, or has been followed by frequent exacerbations. When operation is resorted to, the operation of choice should, of course, include excision of the ulcer. In ulcer at the pylorus, a Finney pyloroplasty, the Kocher operation, or some similar procedure is preferable, but where none of these procedures is practicable, excision with gastrojejunostomy must be done. While many cases of gastric

ulcer have been reported cured by simple gastroenterostomy, with or without artificial closure of the pylorus, it is extremely doubtful whether this operation is more than a palliative measure, accomplishing no more than merely neutralization of the hyperacidity. It must not be forgotten that the careful postoperative treatment, upon which the success of operation so largely depends, and which must be continued for at least six months to a year, should be the same treatment given for an ulcer not operated upon.

2. *Rest of the affected part* may be procured in a number of ways. Of these, proper diet is probably the most important. The food taken, while nourishing, should be concentrated, unirritating, and easily and completely digestible. In the beginning, feeding every three hours of milk, with the addition of raw eggs (three or four a day), cereals, gelatin, simple crackers or stale bread, with plenty of butter and olive oil, will be sufficient. After a couple of weeks of this diet, gradually other food-stuffs may be added, beginning with vegetables and fruits. Meat should not be allowed for six or eight weeks at the earliest, and then only with extreme caution. Condiments and rich soups must always be avoided. Throughout the treatment the patient should get enough nourishment to gain weight steadily.

Rest in bed is always beneficial and may be necessary in many severer cases for the first week or two. As much rest as possible should be taken throughout the treatment, and long hours of sleep should be insisted upon. Rest of the ulcer will also be aided by coating the gastric mucosa and the ulcer surface with a demulcent, protective substance like bismuth subcarbonate in suspension in liquid petrolatum, ten grains to one dram. This should be given about twenty minutes before each feeding, and will be found soothing and slightly laxative in its action.

Neutralization of the hyperacidity is helpful early in the treatment, and is most simply accomplished by giving sodium bicarbonate or milk of magnesia one-half to one hour after feeding, and by a diet rich in albumin, able to combine quickly with large amounts of hydrochloric acid and still not stimulating to gastric secretion, such as the diet outlined above.

Quieting of the gastric hyperexcitability, by means of atropine, given to physiological effect, is also of considerable value. Laxatives are usually necessary, and the encouragement of proper evacuations will help to eliminate reflex irritation from intestinal toxemia. Mineral oil, properly administered, not only acts as an efficient laxative and intestinal antiseptic, but also, in common with other oils, acts as a sedative to the gastric mucosa, tending to diminish the hypersecretion.

Duodenal feeding must be condemned, because the presence of the tube acts as a foreign body in the stomach, and will cause greater excitability of this organ.

3. *To aid nature* in its efforts at overcoming the infection and instituting repair of the injured tissues, the use of tonics may be recommended. The patients are usually anemic and at least somewhat emaciated, and iron and calcium in some form are useful. The most valuable aid, however, is the use of autogenous bacterial vaccines prepared from cultures obtained from the foci of infection, which, in addition to aiding in the clearing up of these foci, has been found by the writer to have often a distinctly beneficent action on the ulcer symptoms.

Vaccines have been tried out by the writer in 38 cases of gastric and duodenal ulcer with fairly constant results. As a rule, a more or less distinct general reaction, with mild chill, feverishness, languor, and general bodily pains, has occurred in from six to twenty-four hours after the injection, together with an exacerbation of the ulcer symptoms. After this a marked improvement has been noted, which improvement was particularly striking when we first began using this treatment, when several cases, which had been very refractory to the usual treatment, began to show immediate alleviation of all symptoms, and went on to apparent cure. A few typical case histories follow:

Case I. J. M., sixty years of age, Irish, married. Family history negative. Had had typhoid fever twenty-five years before. For twenty years before applying at the Brooklyn Hospital Dispensary he had been troubled with his stomach. Attacks of increasing severity and frequency had finally rendered him unfit for work. He was suffering from severe sharp pain in the epigastrium, coming on shortly after meals, worse after heavy food, and very severe at night. He had sour regurgitation and occasional vomiting of sour material. His bowels were constipated. Examination showed a well-nourished man, skin and mucosæ pale, tongue tremulous, teeth markedly pyorrheic, heart moderately hypertrophied, abdomen soft, with marked tenderness at the epigastrium. No masses discernible. The urine was negative, the stool contained occult blood, and the test meal showed evidence of a hypersecretion, with free HCl 60, total acidity 70. After three weeks of the usual dietetic and medicinal treatment the patient still had some pain and soreness in the epigastrium, and considerable belching. A vaccine was then prepared from cultures of the *Streptococcus viridans* obtained from the pyorrhea pockets, and after an initial dose of 100 million bacteria, there occurred a systemic reaction, together with more epigastric pain than he had had in weeks. After gradually increasing doses for two months, and treatment of the pyorrheic teeth, the pain and soreness entirely disappeared, and five months later the patient was eating everything, having no pain, and steadily gaining weight and strength. At that time a test meal examination showed free HCl 13, and total acidity 26, with no evidence of a hypersecretion.

Case II. J. S., 26 years of age, a conductor, unmarried. Family history negative. Had had an attack of fever, headache, and belching six years before. He was a moderate smoker and beer drinker. For eighteen months before applying for treatment the patient had been belching and regurgitating sour water one to two hours after meals, and for eight months had had burning epigastric pain, worse about five hours after his heaviest meal in the evening. This pain was relieved by vomiting, which occurred frequently, and was sour and burning. He had less pain after light food than heavy. His bowels had been obstinately constipated for six months, and he had lost about fifteen pounds in that time. Examination showed a somewhat emaciated youth, with pale skin and acne. His teeth were moderately pyorrheic, and his nose showed an old sinus infection. Examination of the chest was negative. His abdomen was retracted, very tender in the epigastric region, and showed some rigidity of the upper right rectus. The urine was negative, the stool showed the presence of occult blood, the test meal showed free HCl 37, total acidity 65. After ten days of the usual dietetic and medicinal treatment, the patient's symptoms persisted. After an initial dose of 75 million streptococci there was a slight reaction in the form of an exacerbation of the pain and belching twelve hours later, and then the patient began to improve. The vaccine injections were given weekly for three and one-half months, at the end of which time the pain and tenderness had disappeared, the bowels were regular, and a test meal showed free HCl 35, total acidity 50. He subsequently neglected treatment of his nasal infection, and after one year had a recurrence of his ulcer symptoms in a mild degree. He was then more carefully treated, and did not have a recurrence.

Case III. H. H., 51 years old, female, housewife, married. Family history negative. Had had abscess

of arm eighteen years before. Eleven years before had had a hysterectomy and an ovariectomy, followed by cessation of menses, but no nervous symptoms. Seven years previously had had an attack like the one for which she was applying for treatment. Five years previously had had three attacks of pain in the appendix region, but none since. One year previously had been in bed twelve weeks with an attack called gastric ulcer, from which time she had had constant soreness in the epigastrium, with frequent attacks of burning epigastric pain four to six hours after meals, sooner and more severe after heavy food, relieved by food or kummel, and very bad at night. She was very nervous, and afraid to eat. Examination showed a well-nourished woman. Her teeth were normal, her nasal sinuses chronically infected. Her chest was negative. The abdomen was flabby, hypersensitive, and very tender in the epigastric and appendix regions. Otherwise negative. Urine examination was negative, stool contained no occult blood, test meal showed free HCl 32, total acidity 52. After three months of the usual treatment, there was some relief, but frequent recurrence of the pains, worse at night. An autogenous streptococcus vaccine from the nasal infection was then given, the first dose of 100 million causing general bodily pains, and an exacerbation of the stomach pain. After two days improvement was noted, and continued thereafter. The vaccine was continued thereafter at weekly and later biweekly intervals for four months. Since then the stomach has not given much trouble, but the patient has been seen at intervals suffering from nervous symptoms resembling those of the menopause.

Complications.—The complications of gastric ulcer which must be considered are hemorrhage, perforation, disturbances of motility, and carcinomatous degeneration. Hemorrhage, whether manifest, as in the presence of hematemesis and melena, or concealed, as where only occult blood is found in the feces or stomach contents, requires rest in bed until it has disappeared. In severe cases, rest in bed, with ice-bag over the epigastrium, the withholding of all food by mouth, and enough morphine to insure quiet, will usually result in checking the hemorrhage. The use of horse serum subcutaneously may be necessary to check a severe hemorrhage. Gelatin by mouth and calcium by mouth or rectum, are about the safest of the many agents recommended to be used in this way. When feedings are begun, small quantities of iced milk, frequently repeated, should be given at first, and the diet then gradually and cautiously increased. Rest in bed should continue until occult blood has permanently disappeared from the stools. Rectal feeding is of doubtful value, but may be tried where the patient must be kept without food by mouth for a long time. Dextrose or lactose solution is probably the best nutrient. Profuse hemorrhages, which recur and threaten the life of the patient, require opening of the stomach and suture, or better, excision of the ulcer and gastroenterostomy. It is often very difficult to find the bleeding point, even in large hemorrhages, so that operation during the continuance of the bleeding should be undertaken only as a last resort. It is usually necessary to accompany this operation by a saline venous infusion, or transfusion of blood.

Perforation, whether acute or chronic, requires operation as soon as the diagnosis is made. The extent of the operation must, of course, be guided by the patient's condition, the ideal operation being excision or infolding of the ulcer, combined with gastroenterostomy.

Severe disturbances of motility, as in pyloric stenosis or hour-glass stomach, whether caused by internal cicatrices or external adhesions, require suitable operation. Even here excision of the ulcer, with pyloroplasty in pyloric stenosis, and gastro-

gastrostomy in hour-glass stomach, should be done if possible, as gastroenterostomy alone, in a large proportion of cases, has been shown to result in a return of the ulcer symptoms. Where operation is refused, much may often be done to alleviate the vomiting and distress by means of lavage, the ingestion of oil before eating, the eating of small amounts of highly nutritious food at short intervals, and the administration of antispasmodics, demulcents, and antacids.

Carcinomatous degeneration requires operation as early as recognized, or even when only suspected, but not definitely determined. When found to be inoperable, palliative measures such as mentioned in the previous paragraph should be followed out.

Summary.—1. The newer knowledge of the etiology of gastric and duodenal ulcer requires a revised rationale of treatment. It also points out the way to efficient prophylactic treatment.

2. The removal of all infective foci constitutes the most important and practically indispensable procedure in the cure of gastric ulcer.

3. The use of autogenous bacterial vaccines is of value.

4. The early diagnosis of the complications of gastric ulcer is important, so that proper treatment may be promptly instituted.

889 UNION STREET.

A STUDY OF THE INFLUENCE OF ELECTRICITY ON METABOLISM.

BY MATTHEW STEEL, PH.D.,

BROOKLYN, NEW YORK.

(From the Chemical Laboratory of the Long Island College Hospital.)

1. Introduction.—Probably no department of medical science is less clearly understood by most physicians than the influence of electricity on physiological processes. There is a small group of men who are devoting their lives to this interesting field of science and they are discovering many important facts and are applying their knowledge in the treatment of disease with considerable success. The majority of the medical profession, however, do not seem willing to accept the statements made by these enthusiastic workers. This probably is due partly to insufficient training in "physicochemical physiology" and "physicochemical pathology" among medical men, and partly to the fact that many of the electrotherapeutists fail to appreciate the necessity of substantiating their statements with carefully conducted researches. To use the words of Thomas Renton Elliott, "Medicine owes no debt of gratitude to those who teach to her theories without proof."

In reviewing electrotherapeutic literature, one repeatedly finds statements in regard to the influence of a particular electric current on metabolism, yet the statement is rarely accompanied by convincing figures to substantiate the statement. In the French literature one finds a few very carefully performed researches, especially on the influence produced by the high-frequency and static currents.

Influence of High-frequency Currents on the Urinary Secretion.—The three d'Arsonval currents (the autocondensation, the autoconduction, and the direct d'Arsonval) have been used for a number of years for their stimulating influence on metabolism, and their effect on the urinary secretion has been studied by several investigators on patients, on normal people, and, in a few cases, on animals.

The results chronologically cited are as follows:

Apostoli and Berlioz¹ tested the urine of 280 patients who were under treatment by autocondensation, testing in all 781 specimens. They found an increased elimination of total solids, volume of urine, urea, uric acid, and phosphates.

Reale and Renzi²⁰ repeatedly obtained a decrease in the neutral sulphur, and an increase in uric acid and phosphates. They claim that this simultaneous increase of excretion of uric acid and phosphoric acid in the same proportion seems to point to some action of the high-frequency currents on nuclein. In the type of cases which they studied they think the nuclein is probably the original source of the sugar in the urine, and therefore that it is to this action on the nuclein that the favorable results obtained in the use of high-frequency currents in diabetic cases may be explained.

Vinai and Vietti²¹ performed experiments on two normal adults with the autocondensation type of high-frequency current (periods, three days, treatment, fifteen minutes). They obtained the following results: (a) The volume of urine did not appreciably change with one subject, whereas there was a falling off with the other. (b) In both cases the total nitrogen, urea and phosphoric acid were much increased during the period of treatment, returning to normal in the third period.

Denoyes, Martre, and Rouviere²² also studied the effect of the autocondensation current on normal individuals. In general, they substantiated the results of Vinai and Vietti.²¹ They found that this current caused an increase in the volume of urine, total solids, total nitrogen, urea, uric acid, sulphates, phosphates, and chlorides.

Lecomte²³ performed experiments on himself and on rabbits with autocondensation and autoconduction currents. With both types of these high-frequency currents he obtained a rise in body temperature and an increase in the volume of urine, the total nitrogen, urea, uric acid, and phosphates. The increase is more marked on using the autocondensation than after using the autoconduction current.

Static Electricity.—The metabolic effects of the electrostatic bath were studied by Truchot.²⁴ In the electrostatic bath the subject is insulated and placed in connection with one pole of a static machine, the other pole being usually earthed. The electricity escapes from all points of the integument, giving a slight tickling sensation as if the skin were rubbed with gauze. The body is thus traversed by a constant electric current of high tension. Truchot found that the electrostatic bath caused an increase in the elimination of total nitrogen, urea, uric acid, phosphates, and chlorides.

The influence of the negative bath (an electrostatic bath in which the subject is connected with the negative pole) on metabolism was carefully studied by Yvon.²⁵ He used a Wimshurst machine and carried out his experiments on normal adults. Yvon failed to substantiate the results of Truchot.²⁴ He (Yvon) obtained a lowering of the volume of urine and a decrease in the urea, uric acid, and phosphate output. Later Martre and Florence²⁷ repeated the work of Yvon on the effects of the negative bath on the urinary secretion. They likewise found a diminution of phosphates and uric acid, but they obtained an increase in the volume of urine, total nitrogen, urea, total sulphur, and chlorides. No reliable data were found regarding the influence of the constant currents on metabolism as indicated by the urinary secretion.

By carefully studying these and several other less authentic observations, one is impressed with the fact that two or more totally different types of electrical currents may apparently have practically the same effect on metabolism. For example, the high-frequency type of current, whose action is largely thermic, causes an increase of practically the same urinary constituents as the static type of current whose action is largely mechanical. However, as the data were obtained by different investigators, working under different conditions and living on different diets, our comparison may be too hasty. A careful review of the literature indicated that no extensive comparative metabolic study of this kind had ever been attempted before this work was inaugurated.

II. *General Description of the Experiments.*—This investigation consists of seven metabolism experiments, varying from nine to twelve days each. Five types of electrical modalities were employed.

Subject and environment. All the experiments were performed on the author, who is a normal, healthy man, of medium height and weight. During the experiments his life was extremely uniform.

Food. The daily food was practically non-purin, and consisted of bread, milk, cereal, eggs, bacon, potatoes, lettuce, olive oil, vinegar, cheese, fruit, sugar and water. The total calorific value of the diet amounted to 2,850 calories.

Analysis. The urine was kept in sterile bottles and was preserved with thymol. The urinary nitrogen was determined as follows: ammonia, each day; total nitrogen, urea, creatinin, uric acid, and purin bases, at the end of each period on composite samples.

In experiments III, IV, V, VI and VII, the total sulphur, the inorganic sulphates, the ethereal sulphates, and the neutral sulphur were also determined at the end of each period on composite samples.

Analytic methods. Total nitrogen was determined by the Kjeldahl process. Urea was determined by the Benedict method.⁷ Creatinin and uric acid were determined by the methods devised by Folin.¹¹ The purin base nitrogen was determined by Welker's modification of the methods of Arnstein and Salkowski.²⁹ The ammonia was determined by Steel's³⁰ modification of the Folin process. The total sulphur was determined by Benedict's⁸ method. The inorganic sulphates, the ethereal sulphates, and the neutral sulphur were determined by Folin's methods.¹²

Apparatus employed. The faradic sinusoidal current used in experiments I and II was administered with the Wappler Wall Plate apparatus with provisions for galvanic and faradic sinusoidal currents. The autocondensation current used in experiments III and IV was administered with the Meyerowitz unipulsator, which gives a directional current passing into the condensers in series with a solenoid (No. 8 B. and S. gauge copper wire used) 12 inches in diameter, with a discharging spark gap approximately 2 inches in length.

The combined direct d'Arsonval current and autocondensation current with thin dielectric used in experiment V was administered with the Wappler 2 kilowatt transformer of the King model type. The static wave current used in experiment VI was administered with a Van Houten and Ten Broeck Holtz machine. The galvanic sinusoidal current used in experiment VII was administered with the Victor galvanic sinusoidal apparatus.

III. *First and Second Experiments.*—*The Faradic Sinusoidal Current.* This current is an alternating faradic current in which the coil revolves with uniform velocity in the magnetic field. During half of each revolution of the coil, the current is reversed in direction. The intensity of such a current is proportional to the size of the angle between the plane of the coil and the line of commutation.

Physiological Action. The faradic sinusoidal current produces muscular contractions without producing the disagreeable sensations which accompany the simple faradic. It also possesses some electrolytic action and a mild thermic effect.

First metabolism experiment. Influence of the faradic sinusoidal current with moderate frequencies of interruption. The general conditions of this experiment were as follows:

Preparatory period. Three days. During this period no urine was saved. The three days on the selected low-purin diet sufficed to accustom the subject to the food, and it gave ample time for the alimentary tract to get rid of previously eaten food.

Fore period. Three days. Normal conditions.

Treatment period. Three days. Each day during this period the faradic sinusoidal current was administered at a uniform strength for 30 minutes. The secondary coil was placed over the primary at the tenth division of the Wappler scale. The frequencies of interruption were 45 per minute. One metal plate was placed at the back of the neck and the other one on the leg.

After period. Three days. During this period any lingering effects of the treatment were noted.

Analytic results. The more important data of the experiment are given in table I. The discussion of the results will be taken up in connection with those of the second metabolism experiment.

Second metabolism experiment. Influence of the faradic sinusoidal current with rapid frequencies of interruption. The details of this experiment are almost identical with those of the first experiment, and are briefly as follows:

Preparatory period. Three days. Standard diet commenced. No urine kept.

Fore period. Three days. Normal conditions.

Treatment period. Three days. Each day during this period the faradic sinusoidal current was administered for 30 minutes at a uniform strength. The secondary coil was placed over the primary at the tenth division of the Wappler scale. The frequencies of the interruption were 90 per minute. One metal plate was placed at the back of the neck and the other on a leg.

After period. Three days.

Analytic results. The essential data of this experiment are presented in Table II.

Discussion of the Results Obtained in the First and Second Experiments. Fluctuations in the daily volume of urine. The amount of water in the food remained the same each day, yet, as an examination of Tables I and II will show, there was a much higher elimination of urine during the periods of treatment than in the fore periods; the average increase in the volume of urine was 180 c.c. per day in the first experiment and 120 c.c. in the second experiment. The after periods showed a rapid recovery from the diuresis.

Effects on the total solids. In both experiments there was an average daily increase of about four grams of total solids during the periods of treatment. The increase in total solids still continued in the after periods although to a lesser degree.

This increase in total solids shows that the faradic sinusoidal current apparently augments cellular metabolism.

Effects on the elimination of total nitrogen of the urine. As one might expect, after noting the increase in total solids, there was an increase in the output of total nitrogen in the urine voided during the periods of treatment. The increase was on an average about 0.2 gram per day.

Effects on the partition of the total urinary nitrogen. The most noticeable effect on the distribution of the urinary nitrogen was the absolute and relative increase in the creatinin nitrogen during the periods of treatment. This was probably the result of muscular contraction rather than the result of electrolysis. The urea nitrogen was slightly increased in absolute amount, but there was a small relative decrease during the periods of treatment. The absolute and relative excretions of nitrogen in the forms of uric acid, purin bases, ammonia, and undetermined products were remarkably constant through all the periods. There was a very slight increase during the periods of treatment.

Comparison of the first and second experiments. On comparing the data presented in Tables I and II, one is impressed with the uniformity of the results. It would, therefore, seem that within certain limits variations in the frequency of interruption of a faradic sinusoidal current of uniform strength do not appreciably modify its metabolic effects.

Production of urorosein and nitrites. During the course of determinations of urea by the Benedict method⁷ urorosein developed in the specimens voided during the period of the electrical treatment. Herter¹³ has shown a relationship between the development of nitrites in urine and the appearance of urorosein. The specimens which gave the urorosein reaction, apparently as a result of the electrical treatment, responded strongly to tests for nitrites, whereas the normal specimens (which did not contain urorosein) were free from nitrites.

IV. *Third and Fourth Experiments. Directional and Autocondensation Current with Thick Dielectric.* The high-frequency currents of d'Arsonval and Tesla are alternating currents whose direction is reversed over a million times per second. The special physiological properties of these currents were first published by d'Arsonval in 1891.² D'Arsonval distinguishes between an indirect and a direct application of the currents. The indirect method is again subdivided into two methods of administration, the autoconduction and the autocondensation methods. A brief description of administration of these methods is as follows:

Autoconduction. In the autoconduction method the subject is surrounded by a large spiral which is connected with the apparatus, but he is not in actual contact with the conductor. As the currents pass through the spiral, a similar current is induced in the body of the subject.

The spiral or cage solenoid are made large enough to cover the entire body, and are arranged so that the subject can stand or lie down. Strong currents may be made to pass through the body by this method and the subject becomes so charged with electricity that sparks can be drawn from any part of his anatomy.

Autocondensation. When treated by this method the subject becomes one of the two armatures of a condenser. This is accomplished by having the subject lie on a couch, which consists of a long metal sheet covered with an insulating material of suffi-

cient thickness to prevent the passage of sparks. The metal sheet is connected with one end of a d'Arsonval helix. The subject holds in his hands a pair of electrodes which are connected to the other end of the helix. A condenser is thus formed, in which the insulating material is the dielectric and the metal sheet and the subject form the two armatures. This condenser is charged and discharged with every alternation of the current.

I. There is usually very little muscular contraction and the nervous system does not register any impression. This phenomenon is not thoroughly understood, but the usually accepted theory is that motor and sensory nerves respond only to stimuli whose rate of oscillation is less than 10,000 per second, whereas, high frequency currents are alternating currents whose direction is reversed over a million times per second.

The direct d'Arsonval current. This is the simplest method and consists in connecting the subject to the opposite ends of the solenoid by suitable electrodes. The subject's body is thus placed in shunt or derivation, and as the solenoid offers great resistance to the passage of the current, by reason of its property of self-induction, the current passes via the derived circuit of which the subject's body is a part. When currents of large amperage with this type of apparatus are used, the subject's body will soon become unbearably warm, and yet there will be no sensation of muscular contraction.

Résumé of the physiological effects of the high frequency currents. The various investigators of the high frequency currents have established by physiological experiments on men and animals that:

See Weiss,³⁰ also Nernst,¹⁸ Hill,¹⁴ and Keith Lucas.¹⁹

II. They have a pronounced thermic effect, especially the direct d'Arsonval current. In fact, it appears that what physiological effects are produced by these currents are due to the heat into which they are converted in tissues through which they travel. The thermic effect of the d'Arsonval current is rather distinctive in that it comes from within. For example, if we apply the current by means of a pair of metallic electrodes to the opposite ends of a potato, it will be found that the center of the potato will be cooked long before the exterior portion, thereby showing that the greatest heat is midway between the poles. See Nagelschmidt,¹³ Zimmern and Turchini,²² von Zeinek,²³ Schittenhelm,²¹ Bordier, and Lecomte,¹⁵ Bonnoit,⁸ and Somerville.²⁴

III. The number and amplitude of the respiratory movements are increased. This fact was first observed by d'Arsonval,³ and was further confirmed by Lecomte,⁴ also Baedeker,⁵ and others.

IV. The high frequency currents have a pronounced effect on the blood pressure. The autocondensation current is especially valuable from a therapeutic standpoint, owing to the fact that it is remarkably active in lowering the arterial tension. d'Arsonval³ was the first to demonstrate this property. His statements were all reexamined and verified by Baedeker.⁵ Their findings have been corroborated by many others.

V. Metabolism is considerably increased.

VI. There is no electrolytic action. This fact is easily demonstrated by passing the current through an aqueous solution. No electric decomposition takes place.

Third and Fourth Experiments. The general conditions of the third and fourth experiments were the same, and, briefly, were as follows:

Preparatory period. Three days. The diet was commenced, but no urine was collected.

Fore period. Two days. Normal conditions.

Treatment period. Two days. On each of these days the subject received the autocondensation current for 30 minutes. The strength of the current used was 500 mille amp. The blood pressure and pulse rate were noted just before and at the end of each treatment.

After period. Two days.

Analytic results. The essential data of the metabolic effects of the third experiment are presented in Table III, and those of the fourth experiment in Table IV.

Discussion of the Results Obtained in the Third and Fourth Experiments. *Effects on the blood pressure and pulse rate.* Each treatment caused a fall in blood pressure of 4 to 10 mm., and a rise in pulse rate of 2 to 8 beats per minute. The effect on the blood pressure was comparatively permanent. At the beginning of the treatment the subject's blood pressure was a little above normal for a person of his age (34 years), being 135 mm. At the end of the experiments it was 120 mm. and three months later it was 122 mm.

Effect on the volume of urine. In both the third and fourth experiments there was an average daily increase in quantity of urine voided during the periods of treatment of about 300 c.c. over that voided during the fore periods. The quantity voided during the after periods was somewhat less than that voided during the fore periods.

Effects on the total solids. In each experiment the treatment caused an increase of 5 to 6 grams of total solids, as can be seen by a glance at Tables III and IV. During the after periods the total solids were still a few grams more than the amounts eliminated during the fore periods, thereby showing that the improved cellular metabolism continued some days after the treatment had stopped.

Effects on the elimination of total nitrogen in the urine. In both metabolism experiments there was a comparative increase in the excretion of urinary total nitrogen during the periods of electrical treatment. This increase amounted to 0.3 to 0.4 grams per day.

Effects on the partition of the total urinary nitrogen. The absolute excretion of urea nitrogen ran parallel with the total nitrogen, but the relative amounts did not show the same harmony. During the periods of electrical treatment in both the third

and fourth metabolism experiments, there was an absolute increase in the excretion of total nitrogen and likewise of urea; whereas, in the third experiment, there was no increase in the percentage of the total nitrogen eliminated as urea. In the fourth experiment there was an actual decrease in the percentage of the total nitrogen eliminated as urea. *Ammonia, uric acid, purin bases, and creatinin* were relatively and absolutely increased during the periods of electrical treatment in both the third and fourth metabolism experiments. Of these the creatinin showed the greatest absolute and relative increase. The nitrogen in *undetermined products* fluctuated in absolute amounts, but the percentage values were always lowest during the periods of electrical treatment.

Effects on the total sulphur in the urine. The excretion of total sulphur was lowest during the fore periods and highest during the periods of electrical treatment. The trend of the total sulphur elimination was practically the same as that of the total nitrogen elimination. The only period in which there was a relative variance was the after period of the third metabolism experiment. In each of the other periods the amounts of total sulphur rose or fell in perfect accord with the rise or fall of the total nitrogen.

Effects on the partition of the total urinary sulphur. During the periods of electrical treatment, in both experiments, the *inorganic sulphates* were increased absolutely and relatively, the *ethereal sulphates* were slightly increased, absolutely and relatively, and the *neutral sulphur* was slightly increased in absolute amounts but relatively decreased. The variations between the fore periods and the after periods were not pronounced enough to acquire special mention.

Production of uroscin and nitrites. The same phenomenon of the appearance of uroscin and nitrites in the urine voided during the periods of electrical treatment, noted in the experiments with the faradic sinusoidal current, was obtained with the autocondensation current. Neither uroscin nor nitrites were obtained in the fore periods and only slight amounts appeared in the after periods.

V. Fifth Experiment. Combination of the Direct d'Arsonval Current and the Autocondensation Current with Thin Dielectric.—The electrical modality used in this experiment is a combination of the direct d'Arsonval and the autocondensation currents.

A brief description of the method of applying the current used in this experiment is as follows: The subject is seated in a reclining chair, upon which is placed a thin dielectric (a cushion of compressed fiber), under which is placed a metal sheet similar to that used in the autocondensation couch. This metal sheet is connected to one end of the solenoid, and the subject is connected to the other end of the solenoid by a pair of metal handles which he holds in his hands. This arrangement completes the autocondensation part of the apparatus. By having a metal plate, upon which the subject places his bare feet, which is also connected to the solenoid, the direct d'Arsonval current may be applied at the same time.

The general physiological effects. The only factor that differentiates this current from the autocondensation current is its more pronounced thermic effect. This may be attributed partly to the use of a thin dielectric and partly to the combined direct d'Arsonval current.

The fifth metabolism experiment. The general conditions of the previous experiments were followed in this experiment, and were as follows:

Preparatory period. Three days. The diet was strictly adhered to, but no urine was collected.

Fore period. Two days. Normal conditions. This experiment was conducted during a very cold spell in the month of February, 1914, which, perhaps, accounts for the fact that more urine was voided during the fore period of this experiment than during the fore periods of the previous experiments. However, it only tended to make the effects of the experiment more pronounced.

Treatment period. Two days. The total length of the electrical treatment taken on each of the two days of this period was 30 minutes and the current was applied as follows: for 5 minutes, 1500 m. amperes were sent through the feet alone; under this method of application the subject's body acted as a condenser; for 15 minutes, 1,750 m. amperes were sent through the hands and feet. When applied in this manner the combination of autocondensation and the direct d'Arsonval was effected; for 6 minutes, 1,960 m. amperes were sent through the hands and feet; during this part of the treat-

ment the subject's body became uncomfortably warm and the flushing of the capillaries of the wrists become so pronounced that he could scarcely endure the pain in the wrists. For the last 4 minutes, 1,600 m. amperes were sent through the hands and feet.

The blood pressure before the treatment was 124 mm., and after the treatment 118 mm. The temperature was 98° Fahr. before the treatment and 99° Fahr. after the treatment. During the latter part of the treatment the perspiration became visible. After the treatment the visible perspiration soon stopped, but the sensation of unusual warmth lasted for over an hour. Before the end of the first day of treatment the subject became very thirsty, due to the abnormally large amount of water lost through the skin. The amount of urine voided on this day was 905 c.c., which was 305 c.c. less than the average amount voided during the fore period. On the second day of treatment the sensation of thirst was greater than on the previous day, so it was thought advisable to drink an extra quantity of water, about equal to the decrease in urine voided on the first day of treatment. Consequently 300 c.c. extra of water were drunk.

After period. Three days. During this period the extra 300 c.c. of water were still consumed.

Analytic results. The principal data of the fifth metabolism experiment are presented in Table V.

Discussion of the Results.—Effect on the volume of urine. If one were skeptical as to whether electricity has any effect on metabolism, a study of this experiment would convince him that certain types of currents do have a profound effect. In experiments III and IV, in which the autocondensation current was used with a moderate strength of 500 m. amperes and a thick dielectric, the quantity of urine voided during the period of treatment was about 300 c.c. per day more than that voided during the fore period. In this experiment, as was pointed out in the protocol, due to the thermic effects produced by the higher amperage, the thin dielectric and the direct d'Arsonval current, the volume of urine was 305 c.c. less on the first day of the treatment than the average daily volume voided during the fore period. On the second day of treatment, although 300 c.c. extra of water were drunk, the quantity voided was still only 965 c.c., which was 235 c.c. less than the daily average of the fore period. During the three days following the treatment, although the 300 c.c. extra water were consumed, the quantities of urine voided were respectively as follows: 950 c.c., 1,030 c.c., and 1,320 c.c. This gives a daily average for the post-treatment period of 1,100 c.c. If we take into account the fact that 300 c.c. more water per day were consumed during this period than during the fore period, it means that an average of 410 c.c. less water per day was voided as urine during these three days than during the fore period. From this data it is apparent that the d'Arsonval current, if administered in a form that will raise the temperature of the body, will greatly increase the amount of moisture eliminated through the skin and mucous membranes, and that the effect lasts for several days after the treatment has been stopped.

period was just a trifle more than that voided in the fore period.

Effects on the elimination of total nitrogen in the urine. There was an average daily increase in the total urinary nitrogen of 0.45 grams during the period of electrical treatment. During the after period there was a falling off of 0.09 grams daily as compared with the amount eliminated during the fore period.

Effects on the partition of the total urinary nitrogen. The urea nitrogen was relatively and absolutely increased during the period of electrical treatment, the average daily increase during this period being 0.4 grams. Outside of a slight general increase during the period of treatment, there was very little difference in the output of ammonia, uric acid, purin bases or creatinin in any of the periods. The undetermined nitrogen was both relatively and absolutely lowest during the period of treatment. This fact is all the more singular as it was during this period that the total nitrogen was highest.

Effects on the elimination of the sulphur compounds. A glance at Table V shows one that the sulphur metabolism was in accord with the nitrogen metabolism. During the period of electrical treatment there was an increase in the elimination of total sulphur and the bulk of the increase was in the form of inorganic sulphates. The ethereal sulphates did not vary much in any of the periods. The neutral sulphur was lowest, both relatively and absolutely, during the period of treatment, notwithstanding the increased elimination of total sulphur during this period.

Urorosein and nitrites. As in the previous experiments there was a development of urorosein and nitrites in the urine voided during the period of electrical treatment. This phenomenon was apparent, though less pronounced, in the post-treatment period.

VI. Sixth Experiment. Static Wave Current.

*All the sulphur compounds are reported as SO₃.

Effect of the total solids. The amount of total solids did not vary like the volume of urine. The greatest quantity was voided during the period of treatment, which was the period in which the volume of urine was lowest. The increase was about 2 grams per day. The amount voided in the after

The static wave current, perhaps better known as the Morton wave current, is administered as follows: the subject is placed upon an insulated platform; a metal electrode, having been placed upon some part of the subject's body, is connected by wire to the positive pole of a static machine, and

the negative pole is grounded. The intensity of the current is controlled by the length of the spark gap and the size of the terminal balls.

The effect of such a current is local to a marked degree, *i.e.* there will be great muscular contraction immediately under the electrode. The static wave current is essentially a current of high potential. The amperage is very low. Its virtue lies in its ability to cause profound muscular contraction without the pain that would be produced by the galvanic or faradic currents.

Sixth metabolism experiment. The general conditions of this experiment, being similar to those previously cited, were as follows:

Preparatory period. Three days. No urine collected.

Fore period. Three days. Normal conditions. There is nothing special to note about this period.

Treatment period. Three days. Each day during this period the static wave current was administered as follows: a large electrode was placed over the liver and a strong current applied for 15 minutes; then the metal electrode was placed over the kidneys and the current applied for 15 minutes. In both instances the spark gap was 8 inches and the terminal balls 1¼ inches in diameter.

The only sensations observed were the violent muscular contractions beneath the electrode, especially when the electrode was placed over the liver, and the sensation of having the hair of the head standing on end.

After period. Three days.

Analytic results. The essential data of the sixth metabolism experiment are presented in Table VI.

Discussion of the results. *Effect on the volume of urine.* The total volume of urine voided during the three-day period of treatment with the static wave current was 3,870 c.c., as compared to 3,240 c.c. voided during the three-day fore period, and 3,120 c.c. voided during the three-day after period. This shows a relative increase of over 200 c.c. per day during the period of electrical treatment.

Effect on the elimination of total solids. The total solids were very markedly increased on the days in which the static wave current was administered. There was a total of 21 grams more total solids eliminated during the period of electrical treatment than during the fore period; this means an average daily increase of 7 grams. The effect

of the electrical treatment on the total solids was still apparent in the after period, as there was still an average of 3.5 grams per day more eliminated during this period than during the fore period.

Effects on the elimination of total urinary nitrogen. There was an average daily increase of 0.82 grams of total nitrogen eliminated during the period of treatment. This is a greater increase than was obtained by any other modality.

Effects on the partition of the total urinary nitrogen. The urea was both absolutely and relatively increased during the treatment period. The average daily increase for this period was 0.79 grams of urea nitrogen which is equivalent to a daily increase of 1.69 grams of urea. *Ammonia nitrogen*, absolutely, was slightly increased during the period of electrical treatment, but relatively there was little change in all three periods. *Uric acid* was much the same in amount in each period. Absolutely, it was increased very slightly during the period of treatment, but relatively there was no change. *Purin bases*, both absolutely and relatively, were practically the same in each period. *Creatinin* was increased, both absolutely and relatively, during the period of treatment. The nitrogen in undetermined products was eliminated in greatest amounts in the fore period, and in smallest quantities, both absolutely and relatively, during the period of treatment.

Effects on the elimination of sulphur compounds. The total sulphur was eliminated in greatest amounts during the period of electrical treatment. The increase was entirely in the form of *inorganic sulphates*, for there was a slight decrease in the elimination of both *etheral sulphates* and in *neutral sulphur* in this period. (See Table VI.) From the above data one would infer that the static wave current when applied directly over the liver and kidneys, at any rate, markedly increases metabolic function. There is considerable evidence of increased oxidation.

Elimination of urorosein and nitrites. As in the previous experiments urorosein and nitrites were found in the urine voided during treatment and after periods only.

VII. Seventh Experiment. Galvanosinusoidal Current. This current combines all the physiological effects of the other currents. It has marked electrolytic and thermic effects. It causes contrac-

tions of both striated and unstriated muscles. It has strong polar action, and it appears to have a special action on the sensory nerves.

Seventh metabolism experiment. The conditions of this experiment are quite similar to those previously cited. The periods were as follows:

Preparatory period. Three days. No urine collected.

Fore period. Three days. Normal conditions. Urine collected.

Treatment period. Three days.

Each day during this period the galvanosinusoidal current was applied as follows: large felt covered plates, 5 x 8 inches, moistened in salt solution, were placed over the middle of the back and over the abdomen. The strength of the current used was 70 m. ampere, with slow interruptions. The length of the treatment was 30 minutes.

The sensations of heat, pain and muscular contractions were quite marked with this current.

After period. Three days.

Analytic results. The more important data of the seventh metabolism experiment are presented in Table VII.

Discussion of the Results.—Effects on the volume of urine. The total volume of urine voided during the fore period was 3,240 c.c., whereas the total volume voided during the period of treatment (same number of days) was 2,010 c.c. This is an average daily decrease of 410 c.c. for the period of treatment. During the after period there was a total of 2,895 c.c. voided, which is 345 c.c. less than the quantity voided during the fore period.

During this experiment the subject was weighed

that notwithstanding the small quantity of urine voided during the treatment period, the total solids were 2 grams per day above the normal.

Effects on the elimination of total urinary nitrogen. The quantities of total nitrogen excreted in the normal period and in the post-treatment period were almost identical. The amount excreted during the treatment period was 0.26 gram per day above normal.

Effects on the partition of the total nitrogen. There was 0.21 grams more of urea nitrogen, equal to 0.45 gram of urea, eliminated per day during the treatment period than during the fore period. However, the relative percentage of the total nitrogen eliminated in both periods was practically the same. There was a slight increase, both absolutely and relatively, in the nitrogen eliminated as ammonia, uric acid, purin bases, and creatinin during the treatment period, whereas the nitrogen in the undetermined products was decreased, both absolutely and relatively, during this period.

Effects on the elimination of the urinary sulphur compounds. There was an increase in the total sulphur during the period of electrical treatment, the partition of which was as follows: an increase in the total sulphates, a very slight increase in the ethereal sulphates, and a decrease in the neutral sulphur.

Effect on the elimination of urorosein and nitrites. Positive tests for urorosein and nitrites were obtained in the urines voided during the treatment period and the after period. Neither urorosein nor nitrites were found in the urine voided in the fore period.

*All the Sulphur compounds are reported as SO₃.

night and morning and the average of these weighings per period was as follows: fore period, 162 lbs.; treatment period, 161 lbs.; after period, 161 lbs.

Comparing the quantities of urine voided in each period of this experiment with the weight of the subject, one must conclude that the decrease in the amount of urine voided during the periods of treatment and the after period was due to increased perspiration, most probably due directly to the thermic effects of the current.

Effects on the total solids. It is interesting to note that the quantity of total solids eliminated in each period varies inversely with the volume of urine voided. Especially noteworthy is the fact

VIII. *General Comparison and Discussion of the Results.* A comparative examination of the data of all our experiments warrants the following condensed summary of the results of the treatments with the various electrical currents.

Volume of the urine. Disregarding normal variations in quantity, the volume of urine was generally increased by treatment with the faradic sinusoidal current, the autocondensation current with thick dielectric, and the static wave current. The volume was generally decreased by treatment with the combined direct d'Arsonval current and autocondensation current with thin dielectric, and with the galvanosinusoidal current, evidently due to the thermic effect of these currents.

Total solids in the urine. In each of the several metabolism experiments the total solids were relatively high during the periods of electrical treatment. The greatest increase in total solids was obtained by the static wave current, probably due to direct stimulation of the liver and kidneys, as the metal electrodes were placed immediately over these organs. That the increase in total solids is not a direct result of the diuretic effect produced by certain currents is proven by the results obtained with the galvanosinusoidal current and the direct d'Arsonval and autocondensation currents with thin dielectric, for with these currents the volume of urine was subnormal during the treatment period; yet the total solids were higher than in the fore periods.

Total urinary nitrogen. In all the treatment periods the total amount of urinary nitrogen was above that of the normal periods. The daily average for all the normal periods was 8.37 grams and the daily average of all the treatment periods was 8.74 grams. The greatest increase of the total nitrogen was obtained with the static wave current, the smallest with the faradic sinusoidal current.

Partition of the total urinary nitrogen. Urea. In a general way the urea nitrogen ran parallel with the total nitrogen. In all of the experiments, during the periods of treatment, the absolute amounts of urea were appreciably above normal, but it was only in the fifth and sixth experiments that there was a relative increase. The greatest absolute and relative increase was obtained in the sixth experiment, i.e. with the static wave current. The eliminations of urea in the post-treatment periods did not vary very much from normal in any of the experiments.

Ammonia. The tables show that ammonia was slightly increased, both absolutely and relatively, in every treatment period. The average daily amounts of ammonia nitrogen for all the normal periods was 0.49 gram, for all the treatment periods, 0.53 gram; for all the post-treatment periods, 0.49 gram.

Uric acid and purin bases were remarkably constant in all of the periods. None of the electrical modalities seemed to affect the excretion of these constituents to an appreciable extent in the normal individual.

Creatinin was essentially the same as urea in appearing in larger absolute amounts than the normal in all treatment periods. The greatest absolute and relative increase was obtained with the faradic sinusoidal current.

Undetermined. In all of the experiments, except the fourth, the nitrogen of the undetermined products was subnormal in absolute amounts during the treatment periods. Relatively it was subnormal in all of the experiments during this period.

Total urinary sulphur. The sulphur compounds were estimated in the third, fourth, fifth, sixth, and seventh experiments only.

In all of these experiments the amounts of total urinary sulphur were above normal in all the treatment periods, and in all the post-treatment periods with one exception (the seventh experiment).

Partition of the total urinary sulphur. Inorganic sulphates. The absolute amounts of inorganic sulphates were appreciably above normal in every electrical treatment period, although the relative excretion was slightly subnormal in the third experiment.

Ethereal sulphates did not show pronounced

periodic variations in any of the experiments. During the treatment periods their elimination was slightly supernormal, both absolutely and relatively, in the third, fourth, fifth, and seventh experiments. It was subnormal in the sixth experiment.

Neutral sulphur. In general the neutral sulphur exhibited diametrically opposite tendencies to the inorganic sulphates. During the treatment periods there was an appreciable increase in both the total sulphur and inorganic sulphates, whereas the neutral sulphur was relatively lower than normal.

Production of urorosein and nitrites. In each of the experiments urorosein and nitrites developed in the specimens of urine voided during the periods of electrical treatment. None of the specimens voided during the normal periods responded to tests either for urorosein or nitrites. Most of the specimens voided during the post-treatment periods gave mild positive tests for both these constituents.

IX. *Conclusions.* Disregarding matters of detail that have been referred to in connection with the discussion of the data of each experiment, the following conclusions sum up the main results of the research:

In these experiments, in which relatively strong electrical currents of various types were administered to the same healthy adult, a stimulation of the metabolic processes always followed the electrical treatment.

The volume of urine was increased by those currents which do not have a pronounced thermic effect, and decreased by those currents which do have a strong thermic effect. This latter type causes large quantities of moisture to be eliminated through the skin.

All the currents caused an increase in the quantity of solid matter in the urine. The same may be said of the contents of the nitrogen and sulphur in the urine.

The most striking and consistent effects on the partition of the urinary nitrogen were the increase in urea and creatinin elimination during the treatment periods. The greatest increase of urea was obtained with the static wave current and the greatest increase of creatinin with the faradic sinusoidal current. The increased elimination of urea may be attributed, in large part at least, to quickened cellular metabolism, and the increased elimination of creatinin to muscular contractions. The observations pertaining to the remaining nitrogenous constituents of the urine have been summarized above.

The absolute increase of urinary sulphur observed was registered in the form of inorganic sulphates, although the relative excretion of the latter was slightly below normal in Experiment III.

It is especially noteworthy that recovery from the effects of the electrical treatment was always prompt and apparently complete so far as our data indicated. Usually after two days no effects could be detected.

In conclusion it gives me great pleasure to acknowledge my sincere gratitude to Dr. Elias H. Bartley, at whose suggestion these experiments were begun, also to Dr. William Benham Snow, who was kind enough to administer the treatments with his own apparatus in four of the experiments. Dr. Snow's constant advice from an electrotherapeutic standpoint was of incalculable value.

The author likewise wishes to extend his thanks to Dr. Frederick de Kraft, who was kind enough to lend the use of his apparatus and to administer the treatment in Experiment V.

CAN WE DIAGNOSE APPENDICITIS?*

By P. I. NIXON, M.D.,

SAN ANTONIO, TEXAS.

WHEN I was invited to read a paper before this society I at once began to cast about as to what subject I should bring to your notice. My first thought was of several unusual conditions which I have recently met, but further thought induced me to forsake the unusual and to choose the time-old but ever-present subject of appendicitis, for appendicitis, like the poor, we always have with us.

The subject of my paper is "Can We Diagnose Appendicitis?" Our first impulse is to reply most emphatically in the affirmative. On second thought we are a little less hasty in our answer, for we each of us can recall cases of appendicitis (and by appendicitis I mean acute appendicitis) that went begging for a diagnosis, and other cases that we hastened to diagnose appendicitis in which operation or subsequent developments controverted this opinion. Because of these and other similar experiences it seems wise for us to reason together, to take stock of our diagnostic ability and to see whether we should not study all cases with symptoms referable to the right iliac fossa a little more thoroughly or at least a little more intensively.

We are all familiar with the classic picture of a young individual who suffers from abdominal pain—generalized at first, localized later—nausea, vomiting, constipation and fever, and who, on examination, shows tenderness and rigidity over McBurney's point. It is granted without cavil that such a case is readily diagnosed. But as one or more of these symptoms or signs is lacking the diagnosis becomes correspondingly more difficult.

The pain is not always of the characteristic, cramp-like variety, or in the characteristic location; a pelvic, retrocecal, or left-sided appendix, may lead one into many a deep diagnostic pitfall. And certainly no one is so narrow in his perspective as to believe that every pain in the right iliac fossa points to inflammation of the appendix. Tuberculosis of the cecum, tuberculous peritonitis, stone in the ureter, pyosalpinx, extrauterine pregnancy, pyelitis, typhoid fever, pneumonia, intestinal obstruction, intussusception, and right hip-joint disease (notably in children) are some of the conditions that may produce pain in the right lower abdomen. Nausea and vomiting are sometimes absent, and constipation can no longer be regarded as a very important symptom since the laity are so prone to administer a laxative on all occasions and without rhyme or reason. And while fever is usually to be expected, one is not infrequently surprised to find the course of a gangrenous appendicitis to be afebrile and with a normal pulse.

What has been said regarding pain is more or less true in considering tenderness and rigidity; these two very important signs, though well localized, are not always indicative of acute appendicitis. There is one point in eliciting tenderness which I would like to bring out: I refer to Rovsing's sign, which may possibly be unknown to some of you. Rovsing's method consists in making pressure over the left

*Read before the Caldwell County (Texas) Medical Society.

side of the abdomen, in an upward direction, following the course of the colon. The sign is positive when the patient complains of pain in the region of the appendix. This sign, when present, is a great diagnostic help, but it is not always present. Personally I have not seen it in any disease other than appendicitis.

No mention has been made of the value of a blood examination; while its value is not to be doubted, it is not always practicable to have it made. Likewise the presence of a tumor has not been mentioned because it is essential that we do not allow our cases to go on to abscess formation, for only the results of the combination of early diagnosis and early operation can rid the lay mind of the dangers of this disease and the operation for its relief.

It is human nature to make much of our successes; but what of our failures and our mistakes? It has been well said that we learn more from our mistakes than from our successes. It is in this belief that I expose to your criticism some of my own personal mistakes.

CASE I.—S. K., merchant, aged thirty-eight, presented the typical symptoms of appendicitis: colicky pain in the right iliac fossa of five days' duration, nausea, vomiting, and fever. He gave a history of several attacks similar to the present illness. On examining the abdomen, one encountered tenderness and rigidity over McBurney's point. The temperature was 99°, the pulse 90. So positive were we of the diagnosis that a gridiron incision was made. To our dismay, the appendix was free from acute inflammation; it was chronically inflamed and densely adherent back of the cecum. The gall-bladder reached below the navel and was very tense. When opened, an acutely inflamed mucosa and several large stones—one of which was wedged in the cystic duct—were found. This is a lesson, written in stone, on the diagnosis of appendicitis.

CASE II.—S. F., girl, aged 15, suffered for twenty-four hours from nausea, vomiting, fever, and pain in the region of McBurney's point. Tenderness and muscle spasm over the right lower abdomen were the outspoken physical findings. A catheterized specimen of urine contained a few pus cells. This case was so definitely one of appendicitis that an immediate operation was done. The appendix was absolutely normal, even the proverbial "few adhesions" being absent. This was a case of right-sided pyelitis.

CASE III.—M. R., boy, aged 5, during the second week of an attack of measles, was seized with sudden, severe pain in the right lower abdomen. Pallor and nausea were accompanying symptoms. The pain recurred at short intervals and finally morphine was used to control it. The child's face had an anxious expression. On examination of the abdomen one could feel a rounded, only slightly tender mass in the right iliac fossa. Muscles not rigid. Rovsing's sign negative. Pulse 110, temperature 101. At operation a double intussusception was discovered. The ileum had become invaginated into itself and this in turn was inverted into the cecum. (See illustration.) At the apex was found the primary cause of the condition; a Meckel's diverticulum which projected as a sessile growth into the lumen of the intestine.

This case was diagnosed appendicitis. It was thought that an abscess had developed slowly so that the child complained little or not at all. As we look back it is questionable whether such a diagnosis should have been made even tentatively. It at least illustrates that a close, intensive study of every doubtful case is much to be desired even if we know the case to be surgical.

CASE IV.—Mrs H., aged 34, was sent to me with a diagnosis of appendicitis. She gave a history of having had several attacks of pain in the right iliac region associated with nausea and vomiting. The present attack was perhaps excusably considered one of recurring appendicitis. It began two weeks before with rather sudden pain in the region of the appendix. She had a recurrence on two succeeding days and on these days

she vomited. She had several attacks afterwards and a constant soreness was present. The pain was located definitely in the appendix region and was similar in character and location to the pain of previous attacks. This patient had had a disturbance of menstruation: she menstruated normally 25 days before she was seen and had had a slight flow at intervals since. Her temperature was 101°, pulse 120. Anemia was not noticeable. Tenderness over the appendix was definite. Vaginal examination did not reveal any palpable disease. At operation we found a chronically inflamed appendix. The presence of free blood led us to a ruptured and bleeding right tube the size of a small hen's egg.

The slight menstrual disturbances and the rapid pulse should have put us on our guard. We are thus once more reminded that pain at McBurney's point is not pathognomonic of a diseased appendix.

CASE V.—W. K., laborer, aged 60, had had "stomach trouble" for twenty years. Several weeks before he was seen he had a gastric hemorrhage. Two days before, generalized abdominal pain ensued and the next day vomiting and hiccough began. The patient was acutely ill. Pulse 110, temperature 102°. A leuco-

Diagram of double intussusception, originating in Meckel's diverticulum, at the ileocecal valve. (After Kelly & Noble.)

cytosis of 22,000 was present. The abdomen was moderately distended and everywhere there was marked tenderness and a board-like rigidity of the muscles. The rigidity was most extreme on the left side low down. No masses were felt. The area of liver dullness was completely obliterated. There was no dullness in the flanks.

A right rectus incision was made—the incision of choice when in doubt. The cecum was found in the hypogastrium. The appendix lay in the true pelvis on the left side; its perforated tip lay in a pocket of pus, about which there was a beginning local peritonitis.

This case gave a history of gastric ulcer. It was not unnatural to suppose that the fulminant symptoms were due to a perforated ulcer. Certainly the signs on the left side were more suggestive of diverticulitis than appendicitis.

Other cases could be cited, but these will suffice to show that some of us at least cannot always diagnose appendicitis. We are reminded by them of the necessity of weighing every bit of evidence for and against this diagnosis. The man who diagnoses appendicitis in every case in which symptoms and

signs are present in the right iliac fossa will be right more often than he will be wrong, but should he be satisfied with any such rule of thumb? There is an old adage that we find that for which we look, and it has a particularly happy application to the subject of diagnosis; if we are to recognize the occasional case of pyelitis or intussusception which simulates appendicitis it is essential to keep in mind the existence of such conditions and to use all possible means to eliminate them. It is needless to expect every case to present a typical text-book picture; one case may be lacking a symptom here or a sign there, and another may present an array of facts altogether superfluous in forming a composite whole. No one has given expression to this thought more forcefully than Richard Cabot when he wrote, "It should be said with emphasis that in almost every carefully studied case there are one or two facts which stray across the clinical field quite wild and untamed, and never submit to any rational explanation. If a case does not manifest some such symptom, but reels itself off like a text-book account, I always suspect that it is carelessly reported."

If it were permissible to draw any definite conclusions from this informal paper they would be about as follows:

1. We learn much from failures.
2. Every pain in the right iliac fossa does not originate in the appendix.
3. Other local conditions and general diseases may simulate appendicitis.
4. Every case deserves close study, including a careful history and a thorough examination.
5. When all is said and done, we shall occasionally fail to diagnose a case of appendicitis, and more frequently the diagnosis of appendicitis will be made when operation reveals a normal appendix.

205 HICKS BUILDING.

THE NON-SURGICAL TREATMENT OF TUBERCULOUS GLANDS.

By ARTHUR FENWICK HOLDING, M.D.,

NEW YORK.

HAVING observed the good effects of Roentgen rays on tuberculous glands during the past fifteen years it is with some surprise that I have found that this method is little known and seldom advised by the medical profession. The efficacy of *x*-ray treatment in this condition has been demonstrated in surgical clinics, and the literature contains over 1,500 cases successfully treated by this method. Modern text books and the medical profession at large still advise the radical operations that were considered orthodox before the discovery of the therapeutic worth of Roentgen rays. Non-surgical methods, including the *x*-rays should be tried first in the hopes of avoiding operations.

Keen's,¹ Brewer's,² and Chayne-Burghard's³ works in surgery make no mention of the *x*-rays in the treatment of tuberculous adenitis. Choyce's⁴ Surgery mentions the *x*-ray with faint praise. Johnson's⁵ Surgery devotes considerable space to *x*-rays—tuberculin and helio therapy, but advises surgery. Osler and McCrae⁶ advise against the use of *x*-rays on account of skin dangers and possible peripheral spreading of miliary tubercles, from which it would appear that they are not familiar with measurement of *x*-rays for skin tolerance and histological studies of tuberculous lesions under *x*-ray treatment. The *Journal of the American*

*Medical Association*⁷ editorially sanctions non-operative treatment of tuberculous adenitis in children, but does not mention the Roentgen rays.

As early as 1905, Bullett⁸ had collected reports in 226 cases of tuberculous adenitis treated by *x*-rays, 35 per cent. were cured, 40 per cent. improved, 25 per cent. unimproved. In 1907 Crane⁹ called attention to the fact that the opsonic index in cases suffering from tuberculous adenitis who were treated by *x*-rays gave similar reactions to those given by similar cases when given vaccines. He advanced the theory that *x*-ray treatment was a process of autogenous vaccination.

In 1907 von Mutschenbacher¹⁰ published his results in a series of 1,344 cases of tuberculous adenitis treated by *x*-rays, of which number he found it necessary to operate in only 9 per cent.

In 1913 Blaisch¹¹ reported 50 cases treated by *x*-rays in which 50 per cent. were cured, and the same year Fritsch¹² reported 33 cases treated by the same means, in which it was necessary to operate in only 4 per cent.

In 1915 Krecke¹³ reported on 36 cases of tuberculous adenitis treated by *x*-rays in his clinic during the last two years, and stated that since Roentgen ray treatment had been substituted for surgical procedures no radical extirpation of glands had been necessary, the surgical measures being limited to punctures when abscesses formed. The cosmetic results were better, and there were fewer recurrences under *x*-ray treatment than there had been previously under surgical treatment.

Pathology.—That the *x*-rays exert the greatest influence on the lymphatic system of the body was established by Heineke¹⁴ and has been repeatedly verified by other observers. The ultimate effect on lymphatic structures is to replace the lymph tissue with fibrous tissue. The rays also increase the number of lymphocytes present in the circulating blood, and microscopical examination of excised glands that have been treated with *x*-rays show an encapsulating area of lymphocytes surrounding the lesion.

Kuepferle¹⁵ has shown in animals that tuberculous granulations have been controlled by Roentgen treatment inducing a peripheral round celled infiltration and the substitution of fibrosis in place of the active tuberculous lesions. In caseous glands or those that have begun to break down in the center, pus formation as hastened by the Roentgenization so that the lesion rapidly increases in size. Unless forewarned the patient usually becomes frightened at this, thinking that the glands are being made worse by the treatment. They soon "point," and after an incision and evacuation of the pus these cases usually progress uninterruptedly to cures.

The best results from Roentgen therapy are obtained in the advanced caseous lesions or those in which sinuses have formed. That is, in cases in which external drainage obtains.

In the early hyperplastic form of the disease, slower and less brilliant results follow *x*-ray treatment. Patients in whom the periphery of the lesion is ill-defined, edematous, and actively advancing are much less favorable operative risks than when the glands have no periadenitis, are discrete and not active. In cases with and without periadenitis a tentative course of *x*-ray treatment is advisable even if subsequent operation is contemplated. This will reduce the activity of the process, stop peripheral extension and reduce the lesion in size. When the lesion becomes circumscribed it can be removed

surgically if the element of time is a factor. If surgical removal is to be done after the active process has been controlled by Roentgen therapy the operation should be performed before sufficient time has elapsed to allow post Roentgen fibrosis to develop.

If the hyperplastic lesions without periadenitis do not promptly diminish in size under Roentgen treatment surgical removal may be considered. In this class of cases, however, operation will seldom be indicated if thermopenetration and high frequency vacuum electrode treatment are employed as synergists to the Roentgen therapy.

Patients having enlarged tonsils should have the tonsils removed.

The following illustrative cases may be cited:

CASE I.—Mrs. R., aged 26. Patient rather below par physically and extremely nervous. In 1904 developed a chain of enlarged glands on the left side of neck. Consulted surgeon and a radical operation was performed. Within six weeks there were recurrences at the site of operation with sinus formation and also rapid enlargements of the glands on the other side of the neck. Realizing that the patient could not stand a second operation, she was assured by the surgeon that the "swelling was sympathetic" and the patient's relatives were told that there was no hope for the patient's recovery. At this stage I saw the case and urged the surgeon in charge to let me try Roentgen rays. To this he consented. Treatment was started and the patient immediately began to improve. Within three months she was symptomatically well and has never had a recurrence of the trouble. She is alive at the present time—eleven years since being treated.

CASE II.—Mr. S., aged 50. Entered hospital 1905 with a walnut-sized tumor in the left side of the neck which clinically was diagnosed as a round-celled sarcoma in a very active condition of growth. At operation it was impossible to remove all of the tumor, but sufficient was obtained to make a microscopical examination, and the diagnosis of tuberculous adenitis was established. Very rapid enlargements of the glands on both sides of the neck followed the operation. These glands encroached upon the trachea, the patient became cyanosed, the glands enlarged the neck so that the skin line bulged from the jaw to the clavicles and a plunge tracheotomy was contemplated. At my earnest solicitation the surgeon consented to *x-ray* treatment with the remark that "it can do him no harm, he'll die anyway." Under *x-ray* treatment the glands gradually reduced in size, the patient became symptomatically well and remained so for 5 years, dying of nephritis.

CASE III.—Master K., aged 6 years, was considered a case of Hodgkins' disease, having the cervical glands on both sides of the neck involved. Under medical treatment the glands enlarged steadily and it was necessary to do an emergency tracheotomy. At this time some of the glands were also obtained for microscopic examination and the laboratory reported them as tuberculous. This patient was put under *x-ray* treatment and the condition completely cleared up.

These three cases occurring during my early years of practice were dramatic enough to convince the most sceptical observer, and I have treated several cases since that were equally convincing because they were all considered hopeless when the *x-ray* treatment was begun and were restored to perfect health. Seven cases of tuberculous adenitis have come under my observation classified, according to Blaisch, as follows:

I. Hyperplastic type, 16; II. Caseous or purulent type, 23; III. Ulcerated or fistulous type, 30.

Class I.—Three became symptomatically well; 2 were improved and relapsed later and were symptomatically cured by a second course of treatment; 5 disappeared from observation; 5 were improved and later submitted to an operation; 1 unimproved.

Class II.—Nineteen became symptomatically well; 10 disappeared from observation (dispensary cases); 3 were improved.

Class III.—Twenty-five became symptomatically well; 5 disappeared from observation (dispensary cases).

Technique.—The technique employed is that known as Roentgen deep therapy, which has been amply described.^{16, 17} The essentials of deep Roentgen therapy are the use of the Coolidge tube, high voltage, measured maximum skin dosage, cross-firing, and filtration of the rays, given in three to ten series of treatments. If the dose to each skin area is limited to 15 x Kienbock, no disagreeable skin symptoms will follow.

General antituberculosis treatment may be carried on as well as the *x-ray* treatment. In cases failing to respond promptly, hyperemia may be induced by Bier's method or even more effectively by thermopenetration and high frequency vacuum electrode discharges.

Conclusions.—1. The efficacy of *x-ray* treatment in tuberculous adenitis has been demonstrated in surgical clinics, over 1,500 successful cases having been reported.

2. The surgical treatment which was orthodox before the discovery of the *x-rays* and their therapeutic value is still advised by large numbers of the medical profession.

3. Non-surgical methods, including the *x-rays*, deep hyperemia and tuberculin, should be tried before any case is submitted to radical operation.

53 WEST FIFTIETH STREET.

Total Occlusion of the Right External Auditory Meatus.—L. A. Lawrence reports this condition in a woman, aged 31, who was sent to the hospital for pain in the right ear, in all probability due to a carious tooth. Examination revealed occlusion of the right meatus by a smooth partition stretching completely across the space about a third of the depth from the surface. No moisture or discharge was present, and no other deformity was found. The Eustachian tubes were both patent, and râles were heard on both sides through a passed Eustachian catheter. The left ear was normal. The patient could hear an acoumeter two inches from the right ear. The condition, the reporter said, was evidently congenital.—*Proceedings of the Royal Society of Medicine.*

INTRAMUSCULAR INJECTIONS OF MERCURY SALICYLATE IN THE TREATMENT OF SYPHILIS.

BY WILLIAM H. BEST, M.D.

BROOKLYN, N. Y.

ASSISTANT VICE-PHYSICIAN, DEPARTMENT OF CUTANEOUS DISEASE AND SYPHILIS, KING COUNTY HOSPITAL; ATTENDING DERMATOLOGIST, BRADFORD STREET HOPITAL CLINIC; CONSULTING DERMATOLOGIST, BROOKLYN INDUSTRIAL SCHOOL.

IN a recent article on the use of mercury salicylate in syphilis, Nelson and Anderson conclude from the effects of this drug upon the Wassermann reaction that it is improbable that the salicylate alone and unaided possesses any real curative value in this disease, and that its value is so slight as to make it unworthy of the time spent in its administration. To substantiate these conclusions they offer a record of fifty cases, in which the Wassermann was influenced in only a few cases, and in some instances the Wassermann returned to positive after having once been negative. They started the treatment by giving doses of 1½ gr. at weekly intervals, but finding this interval too short gave it every two weeks, and in some cases at even longer intervals. They claim that the patients were kept up to the limit of tolerance, but that none of them was salivated.

My aim has always been to keep the patient up to the point of saturation, and I have accepted as an indication of this an occasional slight salivation, a metallic taste, and a slight sense of tenderness in the gums when the patient bites hard upon the teeth; never, however, permitting this condition to progress to any uncomfortable degree. The patients are instructed previously as to the care of the mouth and teeth, to take a heaping teaspoonful (or even more) of sodium phosphate in a cup of hot water each morning upon arising, and to drink copiously of water. As an extra precaution they are given triturates of atropine sulphate gr. 1/150, and instructed, should salivation at any time become uncomfortable after an injection, to take one and repeat it in eight hours if necessary; and immediately take a liberal dose of epsom salts. This last instruction, I might add, is rarely resorted to.

I have found that, on account of the varying tolerance for mercury in different individuals and the varying tolerance in the same individual at different times, the dose must be frequently changed. It is, however, not an uncommon thing to give as much as three grains of mercury salicylate at one injection. My practice is to start the patient on one grain and increase one-half grain at each injection, until the point of tolerance is reached. The dose at each injection, however, is never decided upon until all the facts following the previous injection that may pertain to the treatment are elicited. From a review of my histories, I find that the dose from time to time, for the same patient, fluctuates from two to three grains according to existing conditions.

As regards the intervals between injections, this also has been a variable quantity; but in my experience patients tolerate their injections very well indeed at weekly intervals. Occasionally it has been necessary to omit a treatment in an individual case, for one or more of several reasons—such as retardation of absorption, induration at the seat of injection, ptyalism, excessive sensitiveness of the gums, or kidney irritation. If however the excretions are properly attended to, and a hot sitz bath

with massage is frequently indulged in, this rarely becomes necessary.

The amount of mercury salicylate administered according to this scheme is decidedly larger than the quantity given by Nelson and Anderson, and since the results obtained by me are so favorable I am forced to the conclusion that their failures were due not to the drug but to the mode of its administration. Naturally, with such intensive treatment, close observation of the patient must be maintained. On account of the known toxic effects of mercury upon the kidneys, the urine should be examined frequently. I make it a routine to examine the urine for albumin at each visit (this requires but a few moments), and if it is present in more than a trace I make a subsequent microscopic examination for casts. Eliciting the urinary findings of a nephritis is indication for a temporary cessation in treatment, with a prompt and vigorous increase in the activity of all the eliminating pathways.

In all latent and active tertiary cases I make it a practice to give potassium iodide in ascending doses, some of the patients taking as high as fifty grains daily. While I do not believe that potassium iodide has any influence upon the spirochete, it is a valuable adjunct to mercury in the treatment of syphilis. I believe, through clinical observation, that it promotes the absorption of the mercury salicylate and lessens the tendency to induration at the seat of injection; and it does that which is even more important, reduces glandular enlargement and induration, thereby continually liberating locked-up spirochetes and permitting the mercury to bring about their destruction more readily.

I offer a résumé of a few cases for the purpose of showing the results obtained by this routine of treatment. The number of cases must necessarily be small, because most patients now are treated with salvarsan and mercury combined.

Case No.	Stage of Disease	Number of Injections	Quantity of Mercury Salicylate	Period of Treatment	Wassermann Before Treatment	Wassermann 3 or 4 Weeks After Treatment	Wassermann 3 Months After Treatment	Remarks
1	Lat.	20	46 gr.	5 mo.	++	+	-	Ulcerations on leg healed readily.
2	Tert.	25	56 gr.	1 yr.	++++	++	+++	Mucous patches and condylomata healed.
3	Sec.	20	48 gr.	5 mo.	++++	++++	+	Patient took Sherwell's mixture between second and third Wassermann.
4	Lat.	20	44 gr.	6 mo.	++	+	-	Two months' rest following course with Sherwell's mixture.
5	Lat.	20	37 gr.	5 mo.	+++	++	+	
6	Continued Lat.	20	43 gr.	6 mo.	++	+	+	
7	Sec.	10	48 gr.	7 mo.	++	+	+	
8	Lat.	20	25 gr.	9 wks.	++++	+++	++	Mucous patches condylomata, syphilitic nodes appeared.
9	Lat.	20	37 gr.	8 mo.	++	++	+	Time treatment irregularly.
10	Tert.	25	55 gr.	7 mo.	++++	++	+	Regular exposure on feet; entirely healed.

Cases 1, 2, 4, 5, 6, 8, 10 had received one or more injections of salvarsan before coming to me for treatment. In Case 2 the patient took a voluntary vacation of several months during the course of the treatment, which accounts for the extended period of his treatment. The patient in Case 3 could not be induced to take salvarsan, therefore mercury treatment was instituted. One could hardly expect the Wassermann reaction to be influenced by such

a short course of treatment; the clinical symptoms, however, yielded with pleasing rapidity. In Case 5, it will be noted, there was but little progress after the first course of twenty injections. The patient was given two months' rest, during which time a teaspoonful of Sherwell's mixture (Hydrarg. chloridi corros. gr. 1/24, liquoris potassii arsenitis 2½, liquoris arseni et hydrargyri iodidi m 2½, syrupi ferri iodidi m 10, potassii iodidi gr. 5 ad 10, syrupi sarsaparillæ comp., q. s. ad fl. dr. 1) was taken after meals. The treatment was then resumed, with the result as tabulated. Case 7 was that of a young woman in pitiable condition, a physical wreck, mouth full of mucous patches, condylomata about the rectum and vulva, extremely jaundiced, with enlarged and tender liver. Under the prevailing circumstances, I was timid about giving salvarsan, for fear of precipitating an acute yellow atrophy of the liver; so preceded the salvarsan with an intensive course of mercury salicylate. Within two months the clinical symptoms disappeared, and the patient's general condition was markedly improved, with a gain in weight of eight pounds. Combined mercury and salvarsan treatment was then instituted, and I have since had the pleasure of getting a negative Wassermann on this patient.

In reference to the vagaries of the serum reaction in syphilis, I want to call attention to the fact that this same phenomenon has been observed with salvarsan as well as with mercury treatment. Is it not possible in certain cases to change a negative to a positive Wassermann by the administration of a small dose of salvarsan? The Wassermann reaction depends upon the presence of specific amboceptor in the serum. If by treatment all the spirochetes that are lodged in accessible places are destroyed, the amboceptor will soon thereafter disappear from the blood serum. If, however, spirochetes are locked up in the enlarged and indurated lymph glands, where the blood supply is not rich enough to bring a sufficient quantity of the particular drug used to destroy all the organisms, then is it not possible that at some time, either during treatment or after treatment has been stopped, spirocheta are liberated and thrown into the blood, and carried to various parts of the body? This causes renewed sensitization and renewed amboceptor production, with a return of those factors in the serum which give a positive Wassermann reaction. I do not think that anyone has maintained that one negative Wassermann is indicative of syphilis cured. Granting, though, that all the cases I report should return to a four plus Wassermann, it cannot be argued that the mercury salicylate injections were not instrumental in bringing about the improvement noted in these patients. All that could be said is that we had not continued our treatment long enough. It is therefore advisable to make repeated Wassermann tests over a period of at least two years, and at the first sign of a positive serum reaction vigorous treatment should again be instituted.

As to the inconvenience to the patient from the intramuscular injections of mercury salicylate, I think this is largely a matter of technique. While it is impossible to make the injections absolutely painless, the soreness experienced and the induration produced can be reduced to a minimum by being certain that none of the suspension of the drug is permitted to enter the adipose tissue. I noted when I first used this method of treatment that women are more inclined to suffer soreness

and induration than are men. After some pondering of this, I concluded that it was probably due to the fact that women as a rule have larger deposits of adipose tissue about the buttocks, and that in all probability my injections were being made into the fat rather than into the muscle. That there was some basis of fact in this conclusion was proven when subsequently I used a longer needle (2½ inches), and much of this soreness and induration was obviated. As a further precaution I withdraw the needle quickly, immediately put pressure over the site of the injection, and massage deeply but gently for a few moments. This prevents the suspension from leaking back along the track of the needle and thereby getting into the adipose tissue. The patient is instructed should any undue tenderness or induration occur to take a hot sitz bath for ten or fifteen minutes each night before retiring, and massage the area gently all the while; this to be continued until the soreness remits. That this technique is fairly satisfactory is proven by the fact that I number among my patients men who earn a living by driving trucks about the city streets, and I should think with them the soreness incident to the injections would be most felt. Yet these patients have complained of but little inconvenience, and have not found it necessary to lose any time from their work.

Taking into consideration all the factors pro and con in the various forms of mercury treatment, I think the intramuscular injection of mercury salicylate offers the most convenient, most easily controlled, most efficient, and most satisfactory of any of them.

1198 BUSHWICK AVENUE.

Medicolegal Notes.

Degree of Care and Skill Required.—The Georgia Civil Code, 1910, section 4427, lays down the rule that: "A person professing to practise surgery or the administering of medicine for a compensation must bring to the exercise of his profession a reasonable degree of care and skill. Any injury resulting from a want of such care and skill will be a tort for which a recovery may be had." The Georgia Supreme Court says that this briefly states the standard by which the conduct of a person claimed to have been guilty of malpractice may be tested. In determining the question of reasonable care and skill by a surgeon the jury may consider the place of operation, the circumstances surrounding it, the situation of the defendant with respect to the operation, and all the facts and circumstances which may be shown by the evidence and which may throw light on the ultimate question: Did the defendant, or did he not, use reasonable care and skill in the performance of the operation? If expert evidence is introduced tending to show the recognized method of performing an operation, or the manner in which it should be performed, it may be considered along with other evidence throwing light on the question. The court preferred the standard required by the code to comparison with an "average" surgeon. And in formulating a charge to the jury it thought it best not to state that the skill of a surgeon includes an ability to perform the operation in an "approved" way. It might raise a question in the minds of the jury as to the meaning of the word "approved" and as to by whom the approval should be made. The court referred to an excerpt from an opinion in a prior case, copied from Taylor's Medical Jurisprudence, to the effect that surgeons should keep up with the latest advances in medical science, and use the latest and most approved methods and appliances, having regard to the general practice of the profession in the locality where they practise. The court thought this quotation was more suited to the reasoning of an opinion than to a charge to a jury, especially in the absence of evidence as to any late advances in medical science, or late and improved methods and appliances in such use.—*Pace v. Cochran*, Georgia Supreme Court, 86 S. E. 934.

THE TREATMENT OF WOUNDS OF THE ABDOMEN CAUSED BY PROJECTILES.

By combining all the statistics presented before the Paris Société de Chirurgie from the commencement of the war up to a certain time, Quénu (*Revue de Chirurgie*, August, 1914-November, 1915) obtained a total of 217 cases of abdominal wounds, not operated upon, with 171 deaths, a mortality of 78 per cent. Later, he combined the results of abstention at the hands of a number of surgeons, and of 53 cases not operated upon there were 29 deaths, a mortality of 54 per cent. Borrowing the figures from the *Lyon Chirurgical* for September 1, he finds one series of 100 abstentions from operation with 100 deaths; another of five cases with five deaths, a mortality in both series of cases of 100 per cent. Adding the figures of these three series of cases together he obtains 375 cases with 305 deaths, a mortality of 80 per cent. We may add here that in the same journal Dupont and Kendirdjy report 40 cases of penetrating wounds of the abdomen treated medically with 40 deaths.

Since he had already shown that certain cases presented as penetrating wounds of the abdomen and cured spontaneously were, in all probability only parietal wounds, Quénu now took up the subject in another way. Instead of further analyzing reports of other observers he got together as many cases as possible catalogued as wounds of the abdomen, examined them all himself, and upon this investigation his paper is based. At Cochin and at Val-de-Grâce he saw 59 such cases, and to these he adds three reported in detail to him by Walther, making 62 cases ticketed as wounds of the abdomen. He found that a good number of the cards which accompanied the wounded bore as the designation of the injury not merely "wound of the abdomen" but "penetrating wound" or "perforating wound," sometimes "transfixing wound"—terms often not justified, as he shows later. In fact, in one series of 25 cases, which had been tagged as penetrating wounds of the abdomen, 13 of the diagnoses were erroneous, 10 being simple parietal injuries and three being thoracic wounds. Quénu recognizes the fact that there may be a great deal of difficulty in many cases in determining whether a bullet has or has not penetrated the peritoneal cavity; consequently he states that it is necessary to be circumspect in affirming that there is a peritoneal penetration, and that here is where

the interventionists have the worst of it in the matter of statistics, for "their operative findings leave no doubt as to the perforation of a viscus while the abstentionists profit by all the errors of diagnosis, and God knows how numerous they are."

In considering the 62 cases he divides them into two main classes: (1) Non-penetrating, where the peritoneal cavity is not invaded and the wound is in the parietes only or passes through the colon outside of the peritoneal reflection, and (2) Penetrating, these being subdivided into (a) simple, where the peritoneum was penetrated but with no perforation of the viscera, (b) with univisceral, and (c) with multivisceral perforations. Of the 62 cases he found that in 25 the wound was in the parietes only and in three the colon had been injured extraperitoneally; there were 5 doubtful cases, in one of which he considered penetration probable, while in four it was very doubtful; there were 29 cases where the peritoneum was penetrated, these being divided into eight of simple penetration, one of probable penetration of the stomach, three of small intestine, five of large intestine, two of intestine without its being possible to determine what portion, eight of the liver, and in two cases visceral penetration was doubtful. Putting aside the non-penetrating cases, the five doubtful cases, and those that had been operated upon before coming under Quénu's supervision, there remained 18 who had received penetrating wounds of the abdomen which had been treated expectantly. Of these, one died on the route and three soon after arrival, thus leaving 14 patients, three of whom soon needed urgent operation. We now have as the result of abstention only 11 cases with penetrating wounds, five of simple peritoneal penetration and six visceral, of which latter one was probably of the stomach, two of the large intestine, and three of the liver. Of the five with simple penetration, four had to be operated upon because of complicating omental hernia. As to the six with visceral wounds he says that the cured wound of the stomach was only a hypothetical wound of that viscus. As for the three wounds of the liver, one resulted later in an abscess in the lumbar region, the two others, both of which were occasioned by bullets, were of slight depth, one evidently being the result of a spent bullet, as this was easily extracted, and the other had its two orifices of entrance and exit close together so that the course of its passage through the liver was short and far from the hilum. Of the two remaining cases involving the large intestine, one was partially eviscerated by the traumatism and the herniated and gangrenous gut was resected, while in the final case the wound of entrance was situated in the right hypochondrium and that of exit under the costal border of the same side and far posteriorly. It is thus seen that but very few of these carefully analyzed cases where penetration was actually determined were cured without ultimate operation. Also in view of Quénu's findings as regards errors in diagnosis—28 non-penetrating wounds out of 62 labeled as such—the validity of the claims for percentage of cures in other series of non-operated cases may be considered as open to serious ques-

tion, without at all impugning the sincerity of the reporter.

As a result of his study Quénu believes that he is justified in drawing the following conclusions: (1) Those wounded in the abdomen who were cured without operation, had in nearly half the cases at least (28 out of 62) non-penetrating wounds. (2) The majority of those who had a simple penetrating wound presented an omental hernia through the wound. (3) The penetrating visceral wounds cured spontaneously are reduced to six, of which one was an hypothetical wound of the stomach, three of the liver with trajectory far from the hilum, and two of the large intestine with trajectory of the projectile homolateral and posterior. (4) These special conditions as to wounds of the liver and wounds of the large intestine spontaneously cured are perhaps to be remembered when one has to determine the indications for operative intervention or abstention. (5) The study appears to bring out evidence, indirect but important, in support of the theory of intervention.

THE MYSTERIES OF MENSTRUATION.

IN spite of a procession of centuries filled with the ingenious theories of scientists, the wild surmises of pseudo-scientists, and the dogmatic utterances of religious cults, the exact nature and function of menstruation is almost as much a debatable question as ever. It was inevitable that such a common phenomenon, the explanation for which was not forthcoming to the laity, even by application to the usual sources of enlightenment, should be a fruitful occasion of superstition. This is true almost universally among the uncultured, but is by no means confined to them; surprising is the incidence of such fancies even among the highly educated.

The most popular conception has always been that this process represented some sort of purification. Whether or not this is due to a masculine readiness to accept a theory that the other sex might be the better for an occasional renovation we do not know. Perhaps the theory had its origin in the fact that even the most devoted cave-husband cherished an unconfessed longing for a little freedom now and then and found it by prescribing that the women of the tribe keep apart during catamenial periods. The modern reverberation of the purification idea is found in the description of menstruation as a shedding of the uterine mucosa so as to leave an untainted field for the ovum.

Dr. Raymond Crawford, in the *Lancet* for December 18, has compiled a number of the superstitions associated with this function. Most of these are founded upon the belief that the menstruating woman is being acted upon by some malign influence and must therefore refrain from coming into contact with those about her or with the sources of food supply. In the South African tribes she cannot drink milk, for if she does the cows will die. Even in the rural communities of Europe and America there is a widespread belief that women during their periods cannot make butter from milk. According to Pliny, seeds which she touches become sterile, vines wither, and other plants turn yellow;

pregnant animals, if touched by her, are likely to miscarry; dogs go mad on tasting the catamenial fluid. Intercourse with a menstruating woman is supposed to have a baneful effect upon the man, and should it coincide with an eclipse of the sun by the moon the result is almost sure to be fatal. In Galela these women cannot enter the tobacco fields, in Sumatra they are barred from the rice fields, in Saigon they employ no women in the opium factories. In Syria they cannot help to salt or pickle, and in Brunswick they may not assist in the killing of a pig. Formerly in the north of France no woman was allowed to come into a sugar factory during certain stages of the refining process for fear of turning the sugar black.

A few of these superstitions allude to some benign effects of the menstrual flow, *e.g.* Pliny says, "If a woman strips herself naked while she is menstruating and walks round a field of wheat, the caterpillars, worms, beetles, and other vermin will fall off from the ears of corn." The North American Indians also believed this. Menstrual blood is alleged to have certain therapeutic effects; the negroes make use of it both as a love-potion and an abortifacient; it has been variously prescribed for carbuncles, plague, leprosy, erysipelas, quartan fever, and gout.

The old savage idea of the malign influence of menstruation and the scrupulous avoidance of women in this state are of course examples of the taboo, that is the interdiction of the unknown and the peculiar. The horror of human blood itself seems to have something to do with these superstitions, for in some cases men who had been wounded were subjected to the same restrictions as the menstruating woman.

THE PRESERVATION OF RED BLOOD CELLS.

RED blood cells are used for so many purposes at the present time, both in the laboratory and for therapeutic reasons, that a good method for their preservation would have a practical value as well as theoretical interest. It is well known that they are very sensitive to changes in their environment, and emulsions can be kept in the cold in isotonic solutions for only a very short time. Rous and Turner (*Jour. Exper. Med.*, 1916, xxiii, 219) have been investigating the subject and have shown that the primary injury is suffered by the cells during the washing which is to separate them from the plasma. The act of centrifugation injures them to such an extent that they break down much sooner than cells that are not submitted to this procedure. For protection during washing they found that one-eighth to one-quarter per cent. of gelatin in Locke's solution protected the cells absolutely against injury not only during washing but even after shaking. During the course of this part of the work they determined that human red cells are much more resistant to shaking than sheep cells, while the cells of the rabbit and the dog, especially the latter, are very sensitive to such trauma. There was also great individual difference in the animals of one species. There was no relation between the resistance to shaking and that to hypotonic salt solutions.

The cells having been washed successfully it was found that the optimum preserving fluid varied with the animal. Since the red cells are almost totally impermeable to sugars it was thought that the addition of some sugar to the solution would be of help in keeping the cells intact. For sheep's cells sufficient isotonic aqueous saccharose was added to Locke's solution to make a 2.8 per cent. solution. Cells kept for three and four weeks in this solution were used for Wassermann reactions and were found to give the same hemolytic titer and same results as fresh cells. Dog's cells were kept for from five to twelve days in a saccharose-dextrin-Locke's fluid containing 1.6 to 2.7 per cent. of the sugar and 2 per cent. of dextrin. Human cells were kept in Locke's solution containing 4.9 per cent. of saccharose.

The authors then tried to see if they could not devise a mixture which would keep the blood without washing the cells and found that when three parts of blood were drawn directly into a mixture of two parts of isotonic (3.8 per cent.) sodium citrate and five parts of isotonic (5.4 per cent.) dextrose solution, the red cells could be kept intact for four weeks. The blood and solutions should of course be sterile. In order to determine the ability of these cells to functionate they used them for transfusion experiments in rabbits and found that blood preserved in mixtures of sodium citrate, saccharose, and water for fourteen days functionated so well that the animals showed no disturbance. Cells kept for longer periods, though intact and apparently unchanged when transfused, soon leave the circulation. Animals in which this disappearance of cells is taking place on a large scale, remain healthy save for the anemia due to the bleeding.

FOR NATIONAL QUARANTINE.

THE belief has gone abroad that the quarantine at this port has been transferred to national control and much satisfaction has been expressed thereat. Unfortunately this is not yet the case and the transfer is even now being vigorously opposed by certain politicians who are loath to see \$300,000 worth of patronage, for that is about what it costs the State to maintain the quarantine service, taken away. Governor Whitman, who is loyally endeavoring to bring about this most desirable change, recently appointed Dr. L. E. Cofer of the U. S. Public Health Service quarantine officer of the port, that being as near as he could come to putting the station under national control without action by the State Legislature. At his recommendation a bill known as the Mills Bill, Introductory No. 332, has been introduced into the State Senate and will probably be voted upon before long. The MEDICAL RECORD has repeatedly urged the desirability and even necessity of the control of quarantine of the entire country by the Federal Government and this can now be brought about if the medical men of the State, and especially of this city, will make their influence felt in the matter.

The transfer would be rational, for the New York quarantine is not for local protection only, but exists in the interest of the nation even more than

of the city or State, since of the eight or ten hundred thousand immigrants who normally enter at this port every year the great majority does not stay here, but is distributed throughout the Union. It is manifestly unjust, therefore, that the State should be burdened with the expense of this national work. Moreover there are certain international quarantine regulations which can be effected only by officers of the general government, and the United States government cannot promise that these regulations will be enforced if it has no control over health matters at its largest port of entry. Another manifest advantage of national control is that it would always be possible to reinforce the quarantine staff here with an army of experienced health officers in case of emergency, as when there was danger of an epidemic of cholera, typhus fever, plague, or other infectious diseases being introduced.

The opposition to this transfer is, however, active as well as powerful, and those in favor of it must bestir themselves if they would carry their point. They should write in support of the measure to Senator Henry M. Sage, chairman of the Finance Committee, and also to Governor Whitman, and should write in such numbers that there can be no doubt of the will of the medical profession of the State. The time to write is now.

ADDISON'S DISEASE.

It is admitted at present that while this affection is due to an insufficiency of adrenalin, it cannot be cured by feeding with adrenal substance. Some unknown component is doubtless involved, so that it will be necessary to combine other internal secretions, either synergists or antagonists of adrenalin before we can hope to effect cures. The occasional familial incidence of Addison's disease points to some deep-seated organic substratum. At a recent session of the Aertzlicher Verein of Hamburg (*Deutsche medizinische Wochenschrift*, December 16) Neumann reported the third case in a single family. The malady was primary and not due to tuberculosis of the adrenals. The skin and mucosæ showed the characteristic melanosis, there was asthenia, with increased tolerance for grape sugar and absence of adrenalin glycosuria. Adrenalin was present in the blood serum, but in diminished percentage, as shown by the frog's eye test. The patient is still living, but one of the brothers who came to autopsy was found to have primary atrophy of the adrenals.

GASEOUS GANGRENE.

GASEOUS gangrene has been a condition prevalent in trench warfare and one by no means easy to treat successfully. Dr. Kenneth Taylor, pathologist to the American Ambulance, Neuilly, Paris, has conducted a series of experiments in order to find out which are the factors responsible for gaseous gangrene (*Lancet*, January 15, 1916) and has concluded as follows: (1) The gas produced by *B. aerogenes capsulatus* is of little or no importance as a toxic factor. (2) The mechanical action of the pressure produced is usually, if not always, the most important part of the infection. To it may be charged the development of highly pathogenic possibilities in a usually rather innocent infection. It

brings about (a) the death of the tissues from the resulting anemia produced by a pressure much higher than that of the circulating blood; (b) the actual mechanical fragmentation of the tissues, especially muscle; and (c) the mechanical scattering of the infection. (3) One of the chief problems in the treatment of the infection is that of establishing drainage for the escape of the gas before the pressure has resulted in the death of the tissue.

News of the Week.

City Death Rate.—For the week ending February 26, the death rate in New York City was 15.20 per 1,000 population, as compared with 14.52 for the same month of last year, the actual number of deaths being 1,628 and 1,518 respectively. The number of deaths during the week was exactly the same as during the previous week. Fewer persons died of contagious diseases, as compared with the same week of last year, but the deaths from influenza and respiratory diseases were slightly increased. Organic heart disease and nephritis caused 407 deaths, as compared with 356 during the same period of 1915, while the deaths due to tuberculosis were increased by 11; this increase, however, was entirely due to the increase of population. During the first nine weeks of 1916 the death rate was 16.03, as compared with 14.77 for the corresponding period of 1915.

Health of the Canal Zone.—The report of the Chief Health Officer of the Panama Canal states that during the month of December, 1915, the total number of deaths from all causes among employees was 17, of which 14 were due to disease, giving a death rate from disease of 5.01 per 1,000, as compared with 5.96 for the preceding month and 3.64 for the corresponding month of last year. Among the white employees only one death occurred, and this was due to cirrhosis of the liver; among the colored employees, pneumonia was the chief cause of mortality. The constantly non-effective rate among employees was 10.31, compared with 9.79 for the preceding month and 10.57 for the corresponding month of 1914; 9 per cent. of the total non-effective rate was due to malaria. The admission rate to hospitals and the death rate for disease for black employees were 135.18 and 5.37 per 1,000, as compared with 283.88 and 2.65 for white employees. Among the population of the Canal Zone, amounting to 31,598, there was a total of 38 deaths, of which 35 were due to disease, giving a death rate per 1,000 of 13.29, as compared with 11.14 for the preceding month, and 12.37 for December, 1914. In Panama City, with a population of 60,373, there were 156 deaths due to disease, a rate of 31.01 per 1,000, and in Colon, which has a population of 29,331, the deaths from disease numbered 59, giving a rate of 24.13. The work of sanitation was carried on as usual through the month. On December 10, 1915, two cases of yellow fever were found at Balboa quarantine on a vessel from Buenaventura, Colombia. One patient died in Ancon Hospital four days later, and the other was discharged well.

Two Medical Jubilees.—Dr. Lewis Stephen Pilcher of Brooklyn was graduated from the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1866, and it is purposed by a number of his friends and colleagues to celebrate the occasion in a fitting manner. Dur-

ing the second week of May the physicians of Brooklyn will, in honor of Dr. Pilcher, hold a series of clinics, lectures, etc., the full program of which will be announced later. The celebration is in charge of a committee of which Dr. W. F. Campbell of Brooklyn is chairman, and Dr. W. A. Sherwood, secretary.

Dr. Charles H. Rice of Fitchburg, Mass., was the guest of honor at a banquet given by his colleagues on February 26 to celebrate his fiftieth year in the practice of medicine. Dr. Rice was graduated from the Harvard University Medical School in 1866, and has practised in Fitchburg continuously since then.

Harvey Society Lecture.—The eighth lecture of the series will be held at the New York Academy of Medicine, 17 West Forty-third Street, on Saturday evening, March 11, 1916, at 8.30 P. M., by Prof. Henry A. Christian, Harvard University. Subject: "Some Phases of the Nephritis Problem."

Women in the Columbia Medical Department.—The trustees of Columbia University, at a meeting on Monday of this week, voted to admit women as students in the College of Physicians and Surgeons as soon as the medical school buildings can be altered to adapt them for that purpose.

Memorial Tablets at Beth Israel Hospital.—On Sunday, March 12, ceremonies will be held of the unveiling and dedication of memorial tablets to Dr. Abram Brothers and Dr. Archibald Isaacs, lately members of the medical staff of Beth Israel Hospital.

Nurses Graduate.—Thirty-eight nurses were graduated from the Training School of the New York Hospital on March 1, after completing a two years course of training.

Fewer Street Accidents.—During January, 1916, 1,368 street accidents were reported by the Police Department, a considerable decrease when compared with the same month of last year, when the number was 1,580. During December, 1915, 1,541 deaths were reported. The fatal accidents numbered 41, and 1,420 persons were injured more or less seriously.

Hospital to Raise Funds.—The Manhattan Eye, Ear, and Throat Hospital, New York, has issued an appeal to the public for help in raising \$290,000 before December 1, to be used in extending the facilities of the institution. The sum of \$125,000 has already been promised contingent on the collection of the remainder of the amount needed. Because of the lack of room hundreds of patients are turned away from the hospital each month, and an increase of at least 30 per cent. in the capacity of the institution is needed.

Hospital Ship Sunk.—The Italian hospital ship *Marechiaro* is reported to have been sunk by an Austrian mine off the coast of Albania recently, with great loss of life.

Club House for Nurses.—Through the generosity of Mr. Vincent Astor, it is announced, the graduate nurses of the New York Hospital are soon to have a new clubhouse situated at 317 and 319 West Forty-fifth Street. The building will be eight stories high, and will contain 150 sleeping rooms, a dining room 42 feet long and 29 feet wide, separated from a clubroom of the same size by a folding partition which can be rolled back so as to throw the two into one for social occasions, a library, offices, etc. It is estimated that the cost will be at least \$160,000.

Gifts to Charities.—The Servants for the Re-

lief of Incurable Cancer and the New York Skin and Cancer Hospital receive bequests of \$3,000 each under the will of the late Mrs. Mary C. Archibald of New York.

Dr. Abraham Mayer of New York, who died last summer, left his medical library and the sum of \$1,000 to the Lebanon Hospital, where he was an attending physician.

By the will of the late Mary E. Flaherty of Atlantic City, N. J., the sum of \$5,000 each is bequeathed to St. Mary's, St. Joseph's, and St. Agnes' Hospitals, Philadelphia, and the sum of \$2,000 to St. Vincent's Home and Maternity Hospital in the same city.

Better Baby Week.—Montclair, N. J., recently finished the observance of a Better Baby Week. Lectures were given in the schools, an exhibition of nurseries, dairies, foods, and methods of caring for infants was held, and the pastors of many of the churches cooperated by speaking on the subject from their pulpits. The week just closing has been observed as Baby Week in New York.

Fertig-Hamilton Bill Endorsed.—The Department of Health of New York City is giving hearty support to the bill introduced into the Legislature simultaneously by Assemblyman Fertig and Senator Hamilton, which aims to compel the patent medicine manufacturers to inform the public as to the exact contents of their nostrums; that is, the proposed measure follows exactly the provisions of the Health Department ordinance and regulations on the same subject. The passage of this bill should do much to suppress the traffic in fraudulent, worthless, and dangerous preparations. There is reason, the department states in urging every citizen to write to his senator and assemblyman to ask for favorable action on the bill, to believe that the indiscriminate use of patent medicines in this country is responsible for at least 150,000 deaths a year.

Journals Combine.—Announcement is made of the merger of the *American Journal of Gastroenterology* and the *Proctologist*, the combined journal to be known as *The Proctologist and Gastroenterologist*. The editorial staff consists of Dr. Rollin H. Barnes, St. Louis, proctology; Dr. Anthony Bassler, New York, and Dr. Lewis Brinton, Philadelphia, gastroenterology, and Dr. A. L. Benedict, Buffalo, dietetics. The new journal will be issued monthly.

Therapeutics of the Zeppelin.—The following is an extract from a letter received by a member of the editorial staff from Norfolk, England: "The Zeppelin raids here have caused no panic; they are regarded in the same light as a thunder storm, for their bombs may strike where you are but probably will not. A clerk in the village chemist's shop remarked recently to a customer: 'It is quite funny how these Zeppelin raids take the people. We notice we never sell Epsom salts for a long time after, not even to old Mrs. H., our most regular customer.'"

Belgian Scholarship Committee.—The Belgian Scholarship Committee, which is a subcommittee of the Central Belgium Relief Fund, appeals to all who are interested in the development and diffusion of knowledge and art to contribute to a fund to be used in assisting the scholars, research workers, literary men, and artists of Belgium. All scientific, literary, and artistic work is stopped in Belgium; the libraries, universities, and other educational in-

stitutions have been devastated or transformed into barracks; and the stoppage of work means not only a great private loss but also a serious delay in the advancement of knowledge. In order to give to these workers a chance to resume, the Belgian Scholarship Committee is collecting money which will be expended for their assistance in England, Holland, France, or wherever they may happen to be, in a few instances bringing them to this country. Belgian professors have already been temporarily engaged at Princeton, Harvard, Yale, George Washington University, the University of Pennsylvania, Western Reserve University, and the University of Chicago. In one case the honorarium has been partly paid by the Belgian Scholarship Committee, and it is hoped that subscriptions will be sufficiently liberal to permit of the offering of a similar chance to many others. Contributions may be sent to the Belgian Scholarship Committee, John Joy Edson, treasurer, 309 Wilkins Building, Washington, D. C., and in order that the work may be satisfactorily carried on annual subscriptions during the continuance of the war and for two years after are particularly solicited. The committee will also act as a clearing house between American educational institutions and the Belgian scholars.

San Mateo County (Cal.) Medical Society.—At the annual meeting of this society held on February 18 the following officers were elected: *President*, Dr. Wood C. Baker, San Mateo; *Vice-President*, Dr. Joseph Louis Ross, Redwood City; *Secretary-Treasurer*, Dr. Russell A. Moodie, Redwood City.

Helena Leeming Jelliffe, the wife of Dr. Smith Ely Jelliffe, who died on Friday of last week of cerebral hemorrhage, was a woman of unusual ability in many lines of human endeavor. Although not a physician herself much of her literary work was in medicine. She was the translator of a number of works in neurology and psychiatry and was also the writer of many editorial contributions appearing in various medical periodicals, especially in the *Medical News* during the years that her husband was editor of that journal.

Obituary Notes.—Dr. GEORGE D. DRESSER of New York, a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1874, died suddenly at his home on February 23, aged 49 years.

Dr. HENRY WARD GREGORY died at Philadelphia on February 11 at the age of 42 years. He was graduated from the Medico-Chirurgical College of Philadelphia in the class of 1899, and later served for one year as assistant surgeon in the State Hospital at Hazleton, Penn. He was a member of the Philadelphia Medical Club, the Philadelphia County Medical Society, and the Medical Society of the State of Pennsylvania, and was a Fellow of the American Medical Association.

Dr. CHARLES WHEELER MORSE of Salem, Mass., a graduate of Boston University School of Medicine, Boston, in 1889, died at Westboro, on February 14, after a long illness, aged 49 years.

Dr. FRANK WILMONT MORSE of Thorndike, Me., a graduate of the University of the South, medical department, Sewanee, Tenn., in 1903, died at his home, from pleurisy, on February 6, aged 36 years.

Dr. RALPH C. APTEG of Grand Rapids, Mich., a graduate of the University of Michigan, department of medicine and surgery, Ann Arbor, in 1902, died at his home, after a long illness, on February

13, aged 40 years. Dr. Apted was a member of the American Medical Association, the Michigan State Medical Society, and the Kent County Medical Society. He was for many years the head of the Grand Rapids Health Department and was senior medical officer of the Michigan National Guard.

Dr. THEODORE KEUNE of New York, a graduate of the College of Physicians and Surgeons, New York, in 1878, visiting physician to the Harlem Hospital and a member of the American Medical Association and the New York State and County Medical Societies, died at his home, on February 26, aged 63 years.

Obituary.

WILLIAM LOUIS RODMAN, M.D.

PHILADELPHIA.

DR. WILLIAM L. RODMAN, president of the American Medical Association, died of pneumonia at his home in Philadelphia on Wednesday of this week. He was born in Frankfort, Ky., September 7, 1858, and was graduated from the Jefferson Medical College in 1879. After a term of service at the Jefferson College Hospital he entered the medical corps of the U. S. Army, where he remained two years. He then began practice in Louisville, where he was demonstrator of surgery in the medical department of the University of Louisville from 1885 to 1893, and professor of surgery in the Kentucky School of Medicine from 1893 to 1898. The latter year he was called to the chair of surgery in the Medico-Chirurgical College of Philadelphia; he was also professor of surgery and clinical surgery at the Woman's Medical College of Pennsylvania since 1900. He was a member of the American Surgical Association, the Pennsylvania State Medical Association, the Kentucky State Medical Society, the Philadelphia Academy of Surgery, the Philadelphia Pathological Society, and the International Surgical Society. He was elected to the presidency of the American Medical Association in 1914, assuming office at the San Francisco meeting last June. He was also in 1902 president of the American Medical College Association.

Dr. Rodman was a surgeon of unusual ability, especially interested in the subject of the early diagnosis and treatment of cancer, upon which he had written much. He was also active in advancing the interests of his profession both ethically and materially, and was one of the most energetic promoters of the movement for a national medical license examining board. He was a man of sterling integrity, strong in friendship, a ready writer, an agreeable speaker, and of pleasing manner. In his death the medical profession of America suffers a grievous loss.

Correspondence.

OPPOSITION TO THE HEALTH INSURANCE BILL.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Your editorial in the issue of March 4, on the Health Insurance Bill, known as the Mills Bill, is so unjust that I feel that I must take exception to it. Your statement that the action of the Committee on Legislation of the County Society was an affront to the special committee appointed to study the subject is hardly in accord with the facts. Cer-

tainly no affront was intended and apparently the members of the special committee did not so consider it for more than a majority were present at the meeting which you criticise. If they did not vote in favor of the report they did not express themselves as opposed to it, for it was unanimously approved by those present.

You say that the action was "ill-timed and ill-advised" that there is "no need for hasty action" and that "every one knows it has little chance of enactment at the present session of the legislature." Our information is that the present sponsors of the bill are making every effort possible to secure its enactment and are on record as saying that they will get it through if they can.

It is my personal opinion that this bill is one of the most iniquitous and unjust efforts that have as yet been made to place class legislation on the statute books, but, be that as it may, it is a measure that, in the present form, is calculated to work harm to the medical profession, and as such is one that the Committee on Legislation should bring every effort to bear, to defeat. The profession has a right to expect that its representative medical society shall be on the alert to protect its interest, and it also has a right to expect that one of the representative medical periodicals shall at least be just in its criticism of the profession.

FRANK VAN FLEET, M.D.

[There was no criticism of the medical profession in the article to which our correspondent takes exception.—ED.]

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WOUNDS OF CHEST—SURGERY—HEMOTHORAX—FLUID OR CLOTTED—STERILE OR INFECTED—DRY PLEURISY — ADHESIONS — COMPLICATIONS — SEPSIS —TREATMENT—OBITUARY.

LONDON, Feb. 12, 1916.

ON the conclusion of Sir J. Rose Bradford's address on "Gunshot Wounds of the Chest," reported in my last, Capt H. G. M. Henry spoke on the pathology and bacteriology of these injuries as they had come under his observation at a base hospital. He had made 100 post-mortem examinations besides experiments on animals and the usual routine laboratory investigations of the specimens. In six cases death was due to injury of the vertebræ and spinal cord. Of the 94 other cases 78 had hemorthorax; in only eight of these last death was due to simple bleeding; the other 70 were complicated in 26 by damage to viscera and in 44 by sepsis. The typical post-mortem appearances were next described by Dr. Henry. In a few hours primary coagulation of the effused blood and deposition of fibrin occurred, followed by exudation and a secondary clotting caused thereby. The lung submerged in extravasated blood collapsed, the stages of this collapse being more rapid and its degree more complete than is met with in pleuritic effusion. The part of the lung which was not submerged was highly emphysematous. The line of demarcation between this part and the hemothorax below it varied much in obliquity. In septic hemothorax the pleura and the lung become covered with fibrin—a secondary point—and this may spread throughout the pool of blood. In anaerobic infection the hemothorax often but not always has a foul smell. Anaerobic organisms and streptococci account for the great majority of infections.

Capt. Morriston Davies of University College Hospital next read a paper on the surgical aspects of these injuries, dealing with them in certain groups which had given him some satisfactory results. Blood in the pleural cavity, he found, may remain fluid, or may form a clot, or may be mixed with serum or gas through infection. In wounds by shell the accumulation may be the result of extensive laceration of tissue as in fractures of the ribs. The clot generally adheres along one side at the point of entry, or of exit, or to broken bits of rib, or to the diaphragm or detached bits of metal. But if a penetrating bullet has caused the wound the blood will very likely remain fluid. In such cases there is a deposit of fibrin accumulating mostly in the costovertebral sulcus and over the diaphragm. Clinical examination will not show whether the blood is clotted or still fluid, though if clotted it will hardly give the horizontal shifting upper level of fluid, nor will it pulsate synchronously with the heart. But this aid to diagnosis is available only before a secondary effusion has taken place or considerable separation of serum from the clot. When air is present it is probably derived from a wound of the lung. If small in quantity it is not of great prognostic import, but a large amount may be serious on account of complications, such as displacement of the heart, compression of lung, or development of infection from bronchial secretion, or from gas-forming organisms. Captain Davies passed on to the treatment of hemothorax—fluid or clotted—sterile, or infected, and so to pneumothorax, on each of which he made some practical remarks. He then referred to the acute pain which often persists for days, due to dry pleurisy set up by a bullet passing through the chest wall and which, he said, can be immediately relieved by separating the two pleural layers by gas—either air, oxygen, or nitrogen, no matter which, as it is only required for a few days. Some 200 c.c. more than needed to abolish the pain should be used so as to allow for absorption. The parietal pleura being acutely inflamed, it is more than usually necessary to carefully anesthetize the track of the needle.

Some discussion followed, in the course of which Lieut.-Col. Hale White, who had seen about 50 cases, none of them fatal, said many cases of bullet wounds of the chest caused little suffering. The dyspnea was often out of proportion with the physical signs; in some cases it seemed partly functional only. Hemoptysis was uncommon. It had not recurred except in one case. Aspiration was required whenever the fluid amounted to 20 oz. The chief trouble was collapse of lung, and patients should be taught to re-expand it by breathing exercises and short walks uphill. Dr. Murray Leslie endorsed this view and spoke of the advance made by the extension of aspiration. Dr. C. MacMahon said the points of treatment were (1) to prevent pleural adhesion and break down any existing by gradual movements; (2) to enable any collapsed lung to regain its normal condition; (3) to reduce hemothorax or pneumothorax; (4) to restore shape of chest walls; (5) to assist discharge of pus by increasing inflation; (6) to improve the general condition by tonic exercises and overcome breathlessness on exertion. He strongly advised bending the body laterally away from the affected side, thus partially collapsing the sound lung and compelling the other to inflate to some degree. Dr. Poynton spoke of cases with some fever perhaps rather obscure, and

said caution was important, as they often cleared up with a little patience and operation was spared.

Sir Francis H. Lovell, dean of the London School of Tropical Medicine, died on the 28th ult. in his seventy-second year. He qualified in 1866, was appointed colonial surgeon at Sierra Leone in 1873, became P.M.O. and president of the General Board of Health of Mauritius, where also he was a member of the Legislative Council. Later he was surgeon-general and member of the Executive Councils of Trinidad and Tobago. He was knighted in 1900 and retired from the colonial service in the following year. The University of Birmingham made him Hon. LL.D. in 1911.

The death of Sir Clements Markham is yet another sad warning of the danger of reading in bed. Yet I suppose many will persist in the habit, confident that they will be too careful to become victims. It is stated that Sir Clements had the electric light in his room so there was really no need for a lamp or candle.

Sir George A. Pilkington died on January 28 at Southport, where he practised for some years and was twice elected mayor. He entered Parliament in 1885, but was defeated in the next year's election, but again returned in 1899. He was J. P. and deputy lieutenant for Lancashire, of which county he had been high sheriff.

1. **How May You Assist the Medical Department of the United States Army?**—William O. Owen in an address to the Society of Clinical Surgery of Boston pointed out to the members the difference in the requirements between the army medical officer's training and the surgeon's civilian life in order to show them how they could assist to the best advantage and advance the work of the surgeons in the Medical Department of the United States Army. The army medical officer must be a special class of soldier if he is to render good service, and what is needed is not a man with a knowledge of medicine, but a medical man who has been trained in the special work of a medical soldier. He further stated that for the medical man who is untrained in this particular specialty of medicine to undertake this work is to invite misfortune into his life. He then showed them in what way they could give their services to the army—by caring for the sick in the large hospitals of the rear, by helping the Army Medical Department to select young men for service in the Army Medical Department, by pushing the National Board of Medical Examiners to the full fruition of its desire, and thus eliminating the incompetent from the ranks of the profession. The younger men should be encouraged to go to the camps of instruction now being held in many parts of the United States. Could not they secure a law which would enable them to recommend to the War Department those medical men of the smaller districts whom they knew to be licentiates of the National Board of

Medical Examiners, whom they knew to be competent diagnosticians, men qualified to select recruits for the army under the laws of the War Department? The civilian surgeon had done the work, had stood the strain, and had suffered the pain in the past wars. Would it not be better to be trained? The assistance and interest shown by the civilian surgeon toward the army medical officers would encourage them in their work; it was the duty of all medical men to keep the spotless robes of high purpose and earnest endeavor ever pure and true in order that the men of the oncoming generation may attain to even better, higher things than Lavarán, Ross, our own Reed and Gorgas.

3. **Venesection as a Therapeutic Measure.**—Charles H. Lawrence, Jr., offers a contribution to the knowledge concerning venesection. The general impression heretofore conveyed is that it is a measure only to be used under the most desperate circumstances, and he shows the falsity of this impression. His conclusions are drawn from a series of fifteen cases, in which venesection was performed on twenty-two occasions. 1. Venesection performed under proper indications is not a dangerous measure, especially since the "dose" can be accurately controlled. 2. In the presence of dilatation of the heart, renal toxemia, hypertension, or a combination of these conditions, it may be expected to act more promptly and more surely than drugs. 3. It lowers blood pressure and at the same time produces a more efficient circulation when performed in cases of hypertension, but does not, in therapeutic "doses," lower normal arterial tension. 4. It should never be performed in the absence of definite indications, but should not be withheld until the hope of success for any measure is gone. 5. The amount of blood to be withdrawn is to be decided by the point at which relief is obtained. The error is generally on the side of too small an amount. 6. Repeated blood-letting, when indicated, does not seem to have any ill effects upon the composition of the blood.

6. **What Goiters Demand Operation.**—Frank H. Lahey states that goiter in itself means little or nothing so far as describing the disease goes. It signifies only that there is sufficient enlargement of the thyroid gland so that its prominence is noticeable upon the neck. Much of the confusion in the minds of these physicians who have not followed the advancement in thyroid diseases in the last few years is due to a misunderstanding of this term. Lahey gives six divisions of thyroid conditions, among them the symmetrical enlargement without toxic symptoms which usually occurs in young girls soon after the establishment of the menses, and which type is often sent for operation under the mistaken assumption that all goiters demand surgical intervention. Provided there are no symptoms of hyperthyroidism this type of goiter should be submitted to medical treatment, care being taken to distinguish the appearance of symptoms of hyperthyroidism, when an operation should be advised. He sums up the indications for operation upon the thyroid as follows: 1. For hyperthyroidism (exophthalmic goiter). 2. For pressure (either extra- or intrathoracic). 3. For removal of unsightly enlargements. 4. For malignancy or possible malignancy.

4. **Quinine Urea Bichloride in the Toxemia of Pulmonary Tuberculosis.**—Myer Solis Cohen considers that the treatment of the advanced stage of pulmonary tuberculosis presents the greatest difficulties and disappointments. The most distressing and uncontrollable feature in this stage is the toxemia, and while fresh air, rest, and good food are always indicated they do not constitute the whole treatment. Among the drugs which have a controlling effect on the toxemia is the hydrochloride of quinine and urea. In very many cases the administration of this drug will cause a reduction of the fever and an amelioration of the toxic symptoms. Every patient will not respond to this treatment, and the same patient may respond at one time and not at another. It is not a specific, and one who expects invariably favorable results will be disappointed. Cohen is unable to say why in some instances it gives brilliant results while in others it fails. The drug is given in capsules, and the dose may be five, seven and a half, or ten grains administered every three or four hours, or three times, or twice, or once a day. Doses and interval depend upon the effect produced. After the reduction of the fever a smaller dose and longer interval may be tried, and this must always be done upon the advent of cinchonism. If no effect is produced by a given dose it should be increased.

6. **Syphilis of the Stomach.**—E. D. Holland reports two cases of syphilis of the stomach which are unusual since they simulated gastric cancer and not ulcer. The first case was a railroad conductor, aged thirty-five years, who came to the hospital in a cachectic condition and vomiting after nourishment had been given. Physical examination revealed a dilated stomach, tenderness over the pylorus with a palpable tumor at this point. After an Ewald meal the gastric contents showed free hydrochloric acid absent, lactic acid strong, blood present both red and coffee colored, and microscopical particles of mucous membrane. A consultation ended in the unanimous opinion that it was a cancer of the stomach. An exploratory operation was done, and it was found to be impossible to remove the extensive growth. A piece of tissue was removed, divided, and sent to two different laboratories, and a report from one laboratory called it a tuberculous condition, while the other laboratory reported it to be cancerous. A new head in the department in the hospital decided to try antisyphilitic treatment, and placed the man on small doses of potassium iodide and mercury, with the result that in a month this patient was able to take full treatment, and in ten weeks he was back at work and has remained in good health ever since. This happened before the days of the Wassermann test. The second case was a mountaineer who had had stomach trouble for years. Patient could only drink broth and milk. Examination showed his stomach to be decidedly constricted above the cardiac end. Patient was thin and sallow, and stools showed blood. He denied any syphilitic history. A Wassermann test gave a two plus. He was given an injection of salvarsan five days after his arrival at Hot Springs, and another dose ten days later. At the end of three weeks he was able to eat vegetable soup, finely ground steak, and buttermilk. The blood had disappeared from his stool and he began to gain in weight. It was almost impossible to take an x-ray, as the whole stomach seemed to be so narrowed and elongated that its capacity did not seem to be more than three ounces, and it was almost impossible to get

enough bismuth into it to obtain a shadow. The man improved and would not wait for full treatment, but was able to work about his farm. The foregoing goes to prove that an internist, although a specialist, must be alert to every possible factor that might affect his diagnosis.

2. Transfusion of Blood with Special Reference to the Use of Anticoagulants.—Henry S. Satterlee and Ransom S. Hooker state that they previously have reported a method of transfusing blood by means of specially constructed pipets and cannulas designed for use with either a lining of hardened paraffin or a preliminary internal coating of an anticoagulant solution such as leech extract or hirudin. In this present report they give the results of their experiments during the past eighteen months with various anticoagulants other than paraffin and hirudin, with a view to determining the best anticoagulative agents for purpose of transfusion. In the constantly enlarging field in which transfusion of the blood is being employed the questions which arise concerning the indications and contraindications for this operation, the amount of new blood to be supplied, and the advisability of removing some of the patient's own blood at the time of transfusion are all matters closely concerned with the probable benefit or futility of the operation. The problem is far more complex when it is a question of the benefit to be derived from the transfusion of a so-called normal blood into the circulation of a patient suffering from one or more of the various pathological conditions for which transfusion has been recommended, and they believe this question could be more satisfactorily answered if laboratory methods were available for the detection of other possible grounds of incompatibility than those which are covered by the tests which are now in use. Those who have had experience with the transfusion of blood in varying pathological conditions and by various methods have observed that certain toxic symptoms varying all the way from a slight chill and rise of temperature to marked anaphylactoid phenomena and even death have occasionally resulted as an immediate sequel to transfusion and where the serological tests for hemolysis and agglutination have been entirely favorable. They summarize the results of their experiments as follows: 1. A better

knowledge of the physicochemical changes which may occur in the blood of the recipient as a result of transfusion in varying pathological conditions is needed in order to define more clearly the rational indications for this operation as a therapeutic measure. 2. Certain hypotheses are suggested to explain the occurrence of febrile and toxic reactions following transfusion which cannot be prognosticated by the existing laboratory tests for blood compatibility. 3. Importance is attached to the belief that many of the febrile and toxic reactions not to be explained by hemolysis or agglutination are due to the transfusion of blood which is undergoing coagulative changes or which contains potential coagulative factors such as thromplastin and thrombin. 4. In judging of the safety of any method of transfusion the extent and mode of action of the anticoagulant which is used, the toxicity of the substance, the amount of it which is necessary, and the mechanical technique in transferring the blood are the most important factors to be considered. 5. The employment of an antithrombin such as leech extract or the commercial "hirudin," while appearing to be ideal as an anticoagulant from the physiological point of view, is subject to uncertainty of action and possible danger from contamination with toxic substances. Minimum doses of tested and standardized preparations and optimum anticoagulative technique should be used if such agents are employed. 6. The use of paraffin is theoretically the method of choice in providing an anticoagulant agent for purposes of transfusion and has been found practicable, but not without certain precautions and proper apparatus. 7. Of the inorganic calcium-converting agents which they have investigated experimentally the citrate of sodium and the metaphosphate of sodium are the only substances which exhibit desirable characteristics. Both of these salts, however, have toxic effects which demand consideration of the amounts which can be safely employed for purposes of transfusion. Their experience with sodium metaphosphate is limited to experimental transfusion on animals. 8. Sodium citrate in the proportion of 120 mg. to 300 c.c. of blood, when used with the pipet-cannula apparatus and in the manner described, serves as an effective anticoagulant for transfusion. This proportion (0.04 per cent.) is from one-fifth to one-twenty-fifth of the amount of citrate necessarily employed with other methods. Because of the considerations which have been discussed they believe it to be the best method of transfusion for general use.

3. Reactions Following Blood Transfusion by the Syringe-Cannula System.—Edward Lindeman calls attention to the fact that since the simplification of technique, blood transfusion has acquired considerable popularity. The operative procedure is a life-saving measure and should be regarded as something more than an injection of saline fluid or salvarsan administration, and any tendency to curtail detail of execution to meet the convenience or inexperience of the operator should be discouraged. He takes up the problem of reactions to transfusion, to analyze their cause, and to show the way to prevention. In the first eighteen transfusions which he performed by the syringe-cannula system, preliminary blood tests were made in only two instances. In these eighteen cases there were no chills and no fever reaction above two degrees. The quantity transfused was small—never more than 700 c.c. The donors used were immediate relatives of the patients, and the diseases treated were not primary blood diseases. The conspicuous absence of hemolysis in the absence of blood tests in sixteen of these cases must be attributed to good fortune. In nearly all of the other cases operated upon later in the work, in which blood tests were made, chills and fever were encountered more frequently. In the

first 150 transfusions which were performed by the syringe-cannula system, chills followed by fever were present in about 33 per cent. The quantities transfused were usually 1,000 c.c. or more in adults. The work was done in many different laboratories and in different parts of the country; hence the preliminary blood tests of hemolysis and agglutination were done by many different serologists. In this group three cases of hemolysis occurred, accompanied by chills followed by fever. Hemolysis never occurs without these symptoms unless the patient dies during or shortly after the transfusion. The inference is therefore that these symptom reactions in transfusions are due to hemoglobin set free in the circulating blood. When blood pigment appears in the urine the danger is great and death may follow. The procedure when hemolysis occurs, even when death does not occur, is robbed of its therapeutic value. In the last 155 transfusions by the same system the preliminary blood tests were personally supervised by the writer in all but nine cases. In this last set of transfusions not a single case of hemolysis and not a single death referable to the transfusion occurred. Adults received 1,000 to 1,800 c.c. in each transfusion, and the quantity was always taken from one donor. No foreign substances or anticoagulants were employed in every case. Lindeman draws the following conclusions from his work: 1. The preliminary hemolytic and agglutinin tests when properly performed are reliable. 2. Incidents of hemolysis in transfusion can be eliminated entirely. 3. The reactions which follow transfusion when accurate tests are made are eliminated in all except 9 per cent. of the cases, and in this 9 per cent. chills and fever alone occur. When the quantity is 800 c.c. or less, these symptoms do not occur. 4. By careful, accurate, and complete hemolysis and agglutinin tests, when the work is done skilfully, blood transfusion is robbed of all danger attending its use. This marks a step in advance because of the comparative simplicity of application. He further comments on the fact that in the technique of blood transfusion by the syringe-cannula system the entire mass of blood is outside of the body for a period of between six and ten seconds regardless of the amount transfused. It passes through a minimum amount of foreign material, and embolism or clotting never occurs in transit. No syringe is used for a second filling until thoroughly cleansed with sterile saline solution, and they are cleaned as fast as they are used. Clotting in the syringe cannot occur, and the blood is transferred uninjured exactly as it exists in nature. There is no blind system into which air may leak, and there are no stop-cocks, valves or rubber tubings about which blood may clot. Anticoagulants or foreign substances are never employed.

11. Corpus Luteum Extract in the Nausea of Pregnancy.—John Cooke Hirst reports five cases of pregnancy in which he administered corpus luteum extract for the relief of nausea, and states that his use of this extract for this condition is based on the presumption that there is more than a coincidence between the formation and disappearance of the corpus luteum of pregnancy and the cessation of the nausea. Since the nausea begins to diminish at the time the corpus luteum has reached its acme of development, it may be assumed that there is sufficient absorption from the corpus luteum of pregnancy to account for the disappearance of the nausea. The dose administered by him has been corpus luteum extract 1 c.c. (20 mg.) daily, given hypodermically. The regulation of the amount of dosage is still a matter for investigation, as the above dose may be too small, and will be dealt with in a subsequent report. His results show that he was successful in 80 per cent. of his cases, but one case out of the five failing to react to the

treatment. This one failure shows that dependence cannot always be placed upon this treatment, but he considers it better than any other routine form of treatment, and that probably with increased dosage the method can be shown to have decided value.

12. Diphtheria Carriers.—J. C. Geiger, Frank L. Kelly, and Violet Bathgate report the results of an investigation carried on in six different schools in widely separated communities of California in which cases of diphtheria occurred during the month of October, 1915. A study of the statistics given, in which the personal equation has been eliminated by three persons making the examinations with checking of results, and only typical granular type of diphtheria bacilli being considered positive, proves absolutely that if epidemics of diphtheria are to be controlled by the isolation of carriers, nose cultures must always be taken with those from the throat. Of the 469 cultures made, 32.8 per cent. were positive, and of these positives 87.6 per cent. were found in cultures from the nose, and 28 per cent. of all positives were found in cultures from the throat. The Schick test was used on a group of young adult students in a large university, in order to distinguish between the contacts and the carriers without waiting for the elapsing of the incubation period. With this test it was proved in forty-eight hours that the whole group was immune, and so classed as carriers and relieved of some of the inconveniences attending the quarantine of contacts. None of the carriers developed the disease. In another investigation in which the Schick test was not used, several of the carriers developed diphtheria. Had the test been given, the non-immunes would have been detected and could have been immunized before the development of the disease.

3. The Aerial Conveyance of Infection.—Frederic H. Thomson offers the results of his experiments on the aerial conveyance of infection, which he began on February 12, 1912. The work was carried on in a hospital where 497 patients have been treated during a period of three years and about seven months. The total amount of the diseases treated is 657, as several patients suffered from more than one condition. The space allotted to each patient was 195 square feet of floor space and 15 lineal feet wall space. Scarlet fever, measles, whooping-cough, mumps, erysipelas, tonsillitis, chickenpox, and other conditions were treated, and Thomson has evolved the following conclusions: It must be understood that deductions as to the aerial conveyance of infection do not apply to any other conditions than those obtaining in this special ward, for the results might be different were the beds closer to each other, the ventilation less good, etc. He concludes that scarlet-fever infection and rubella are not carried by air. It has been held for years that the infection of diphtheria is not air borne, and the evidence from his ward corroborated this opinion. While he had an infection of mumps he does not consider it to be air borne. He confesses his doubt as to

whether whooping-cough may be air borne or not. Taking into consideration the propelling power of the cough he considers longer experience to be necessary before a reliable conclusion can be reached. He is satisfied that chickenpox is air borne early in the disease, but that it is difficult to determine the exact time it ceases to be so. He further states as to treatment of chickenpox that although it was safe to treat it in certain stages in this special ward, with all its precautions against direct and indirect infection, it does not follow that it would be a safe procedure to do the same in an ordinary ward when the disease was in a similar or a scabbing stage. He does not accept the view that this disease is infectious until the last scab has separated from the patient's skin, and proved it by introducing seven cases of chickenpox into a ward accommodating twenty patients suffering from scarlet fever. The cases were introduced at stated times and no infection occurred. Enough has been done to lead to economy in the provision of isolation for this disease in hospitals and to show that it is needless to keep the chickenpox patient separate from others for so long as is generally supposed necessary.

5. Prophylactic Vaccination Against Hay Fever.—B. P. Sormani gives an outline of his work and results in the vaccination or active immunization of hay fever with pollen extract in forty-eight cases last year. He gives in part the methods of treatment of Noon and Freeman and shows wherein he disagrees with them. In January, February, or March, he began the treatment by administering a dose of 10 u. p., increasing the amount every week as far as possible in each case. He usually proceeded up to 1,000 u. p., but when the patient showed symptoms of an overdose the increase was very slow or not at all. He prepared the extract by grinding the pollen by rubbing it with sterile sand, and made the extract with distilled water. This extract was not boiled, but was sterilized by adding one-tenth of its volume of 5 per cent. carbol solution, after which salt was added up to 0.85 per cent. Carbolic acid was not added to the extract which had to serve for the ophthalmic reaction, but it was boiled ten minutes, as Freeman does. Fresh vaccine was always used for inoculations. In each case the ophthalmic reaction is determined. Usually a resistance was found of 500 u. p. The reaction is not sharp, nor such as to serve as a guide to treatment. Sormani, however, considers it of the highest importance for diagnostic purposes in the beginning, for by this means he proved that two cases of suspected hay fever were something else. All other patients showed a clear positive reaction. The lowest resistance was 5 u. p., and the highest 5,000 u. p. Almost all of these had been treated in every possible way. In passing it may be observed that this past year was a very severe hay-fever year. Sormani gives his treatment for 1915 as follows: The initial dose was 10 u. p. A little reddening and swelling were observed at the point of injection. The dose was increased every week as follows: 20, 30, 40, 50, 70, 90, and then beyond 100 more rapidly, thus: 150, 200, 300, 400, 500, etc. He desired to carry the final dose up to 1,000 u. p., but found it a high dose. Some patients were cured by a much smaller final dose than 1,000 u. p. He considers it wise to proceed to a higher dosage, if during the preceding immunization nothing has appeared leading to a suspicion of hypersensibility, such as general itching or symptoms of an attack of hay fever. At the end of May the treatment was stopped, but a patient was requested to return if any symptoms appeared. If a patient returned a smaller dose was given, a decrease of 50 or 100 u. p., for fear of a negative phase. In the hay-fever season he began with 5 to 10 u. p., only increasing when necessary up to 25 or 50 u. p. Of fourteen patients treated prophylactically six were com-

pletely cured, six had few of their former symptoms, while two considered no benefit to have been received. Of twelve patients treated phylactically four were completely cured, three felt more or less relief, and five no relief at all. Of nineteen patients treated prophylactically by other physicians all found much relief, while three treated therapeutically found relief.

6. A Case of Febris Colombensis.—G. A. Lurie reports a case of *Febris Colombensis* which he recently observed in Serbia. The patient, an Austrian, had been prisoner in Serbia since December, 1914. Past history negative. He had never been in the tropics. In June, 1915, he began feeling tired and feverish. The fever was of a subcontinuous type, temperature seldom exceeding 103° F., and lasting for five weeks, terminating by lysis. There was no roseola, no spleen enlargement, no complication of any kind. The blood examination at various times for the different typhoid states proved negative; while it agglutinated *B. colombensis*. Ceylon strain in dilutions of 1/40, 1/80, and occasionally 1/160. No hemocultures were done, but the stools examined in the usual laboratory way by plating showed no typhoid bacilli, but four colonies out of twenty-six investigated turned out to be *B. colombensis*, the others being coli and coli-like bacilli. The bacillus is a motile bacterium, Gram-negative, does not liquefy either gelatin or serum. On agar the growth may be typhoid-like, or grow more abundantly than true typhoid. It grows well in milk, rendering the medium acid at first, then alkaline, and often bleaching it, or it may remain permanently acid. On lactose its action is variable. The same strain may at times produce gas and at other times none. This case shows that this disease is not limited to the tropics, but is found in temperate climates and must be regarded as a cosmopolitan disease.

1. "Trench Fever."—McNee, Renshaw, Brunt, and Herringham contribute to the elaborate account of this condition and announce that during the whole time the army has been in Flanders cases of short fever have occurred continually. In a comparatively small number there has been a little bronchitis, or some diarrhea, or tenderness of the muscles or nerves in limited situations. As a rule the symptoms have not included more than the general aches and pains which are the common denominator of all fevers. The patients have been slightly ill, and usually have returned quickly to duty. These undetermined fevers have been from the first the hunting ground of the bacteriologists, who with their laboratories are disposed in a line along the front. After a thorough and comprehensive investigation the following conclusions have been deduced: That the disease is a definite entity, and of infective nature, as is proved by its ready transmission from one person to another by the blood. There are two clinical types of the disease: (a) A short fever of about a week's duration, followed frequently after a few days by a short single relapse; (b) a longer illness characterized above all by the number, sharpness, and periodicity of the relapses. The symptoms of both types are clinically identical, the most constant and characteristic being headache, and pain in the legs and small of the back. The two types described are, in the opinion of

the writers, merely varieties of one and the same disease. In addition to the identity of symptoms, the experimental evidence for this is strong, a typical "short" variety having been shown capable of giving rise to a typical "long" one. The incubation period varies, possibly with the dose of the infective virus introduced. The shortest incubation period in the experimental transmissions was six days, and the longest twenty-two days. The disease is transmissible in every case by the whole blood, whether injected intravenously or intramuscularly; but it is not transmissible by the serum. It follows that the virus is not a "filter passer" in the serum, as all the experiments with filtered serum were negative. The plasma was infective in one experiment, but hemolysis of red cells had occurred, so that the plasma was hemoglobin-tinted. The filtered plasma in another test was not infective. The above results seemed to point to the virus being contained within the blood corpuscles themselves, whether leucocytes or red cells. Blood corpuscles, after washing five times in saline to remove the plasma, were still found to be infective. Very many blood films at all stages of the disease have been examined without a parasite being detected. The blood has been examined fresh, under dark-ground illumination, and dried films have been stained in varying ways, without results. Blood corpuscles were broken down, and the hemoglobin-tinted fluid passed through a filter in an attempt to prove that the virus was an ultra-microscopic one confined to the corpuscles. The fluid was not infective. The only constant morphological change in the blood is the presence of punctate basophilia. The blood counts, differential and ordinary, gave no important results. As regards the means of transmission in nature they have no evidence to offer. The fact that only two classes of men are affected—those from the trench zone and men of the Royal Army Medical Corps—is, however, suggestive. The disease is either contagious from man to man, or what seems much more likely, is carried by one of the common flies or parasites found in the trenches. During the past summer various types of vermin, mosquitos, and flies have been common in the Flanders war zone.

4. **The Physics of a Surgical Dressing.**—A. Primrose says that his attention was called first to the harmful use of impermeable material such as protective, oil-silk, rubber adhesive, etc., by a paper on the physics of a surgical dressing published in a French journal about ten or fifteen years ago. Since then he has had many opportunities in the wards of hospitals to verify the fact. Each day now a new case comes to the wards with an impermeable dressing covering the wound. He has been able to note the great improvement on the omission of that covering in dressings—the custom of impermeable dressings of all septic wounds seems to be widespread. So high an authority as Sir Almroth Wright advocates the use of this type of dressing. In the writer's opinion the best dressing for septic wounds is a moist dressing, and it was found that the hypochlorous acid solution was wonderfully effective. The moist dressing is applied directly to the wound, and over this dry gauze. Everything should be done to favor free evaporation from the surface and absorption into the dressing, which should be frequently changed. He is convinced that it would be greatly to the advantage of the wounded if impermeable protective and oil-silk were entirely removed from the armamentarium of the army. The use of these substances in surgery is very restricted, and as they are employed in military surgery at the present time, the author contends, they generally do very much more harm than good.

Berliner klinische Wochenschrift.

January 17, 1916.

War Literature of Internal Medicine.—Reckzeh begins a serial review of this literature with the circulatory organs, disorders of which make up a large part of the total material. Mild cardiac symptoms are best classed as nervous affections, particularly for the patient's own good, as the knowledge that he had cardiac mischief would tend to make him a hypochondriac. The so-called exhausted heart is an aggravated type of athletic heart. In this condition a number of symptoms do not point directly to the organ—there may be digestive disturbances, lack of appetite, morbid excitability, restlessness, and insomnia. The subjects have precordial anxiety, quickened pulse, heart stitch, etc. In quite another syndrome in which the heart has been seriously damaged by overexertion we may see cyanosis, cold extremities, and a small, soft pulse, which may be rapid or irregular. Arteriosclerosis may rapidly set in as a result of the hardships of war. On the other hand, strange to relate, functional cardiac neuroses sometimes become latent as a result of the changed existence. The x-ray shadow of the exhausted heart shows great variation; this may be normal, or there may be drop-heart or slight dilatation. In the older soldiers the blood pressure may be notably raised. The pulse is regular and steady but often shows diastolic murmurs. An overstrained heart may develop organic lesions, which begin as a rule in the mitral valve and cause either insufficiency or stenosis. There is no commonly accepted rationale for cases like these. There may have been old mercurial lesions or there may be a synchronous rheumatic factor, or the valvular phenomena may be due to dilatation. Murmurs and enlarged percussion area are both often present, but hypertrophy is seldom in evidence, despite the frequency of arteriosclerosis. The latter in the young soldier is often associated with drop-heart and dilatation. It cannot by any means be conceived as a precocious involutary process, but is simply a direct result of active military life. The author says that it is well known that French soldiers have made very considerable use of potassium iodide and of cola with the hope of averting arteriosclerosis. There are, of course, numerous sources of error in wholesale examination of the hearts of soldiers. Certain conditions, such as a high diaphragm, are very seldom thought of in locating the situation of the organ.

The Application of Hard, Filtered X-rays in Dermatology.—Schmidt states that these rays are indicated only when a deep action is desired, notable in hypertrichosis. There is always some danger when using them to the spleen, bone marrow, or gastrointestinal tract. Aside from their indication in epilation, they should never be used on the hairy integument, since they may give rise to an unintended and undesirable shedding of hair. A case is mentioned of psoriasis of the scalp in which unfiltered and medium soft rays had been employed with success. A relapse having occurred he was treated in another city with the hard, unfiltered rays, with exactly opposite results, i.e., hair lost, psoriasis not improved. In a number of conditions in which deep radiation might be assumed to give good results after superficial treatment has proved of no avail the results have been quite negative—for example in epitheliomata. In order to prove that the hard rays have greater biological activity, as is claimed on some sides, it will be necessary to cure eczema and psoriasis which have resisted the action of medium rays, and as far as known, Schmidt says, such results have never been reported.

Critical Remarks on the Diagnosis and Therapy of Ulcus Duodeni.—Boas attacks the correctness of the symptomatology of this condition as taught by Moynihan. He is by no means the first antagonist, as a number of French and Danish physicians have preceded him in his contention while as a class Germans have thus far been non-committal. Boas as a physician sees few cases under operation or at autopsy, while the surgeon naturally draws his conclusions from biopsy, and they are naturally one sided. Medical cases are recognized by the presence of occult hemorrhages. Both have like access to the personal history and for Moynihan this is the crucial factor, being almost pathognomonic. It should include the delayed pain, known as hunger pain, at a certain interval after eating and this phenomenon should show periodicity. It does away with the need of looking for evidence of occult bleeding which would surely be forthcoming. Actual bloody vomiting and melena are also encountered very frequently in the family history, as is also evidence of pyloric obstruction. Biopsy and autopsy, however, often show that a duodenal ulcer is insignificant in itself, being merely associated with pyloric ulcer, cancer, appendicitis, gall duct disease, nephritis, etc. In all these complicated cases a simple personal history cannot be obtained. In Germany there is no "hunger-pain" symptom of a typical character, nor is there a late or periodic element found of any classic sort which could be associated with duodenal ulcer. But certain authors, including Kemp of the United States, have long associated phenomena of this sort with ordinary gastric ulcer, especially of the nonpyloric site. To resume, periodic pain characterizes a great variety of abdominal diseases, "hunger pain" simply points to hyperchlorhydria.

The Dysgiandular Psychoses.—Fauser refers to some of the serological reactions in certain psychoses believed to have a somatic basis in which the glands of internal secretion may be at fault. We should not expect specific reactions, for it is apparent that a dysfunctioning thyroid or brain cortex is a general proposition, and stops short of the how or why involved in individual mental states. The process of dialysis is a crude physical one, and we must wait for the further development of chemical pathology and histological technique before the psychoses can be understood. Moreover the clinical classification in use today is not adapted to the newer lore based on serological finds. The former is highly conservative, the latter progressive. The author regards Abderhalden's theories as a step forward in the sense that Ehrlich's side chain theory is such. The reactions produced, however, are only suggestive, not conclusive; and may be likened in a way to gross microscopic finds at an autopsy. Abderhalden's dialysis procedure is active only with the terminal or end products of digestion of the supposedly specific products derived from this or that organ. It is understood that he is at present endeavoring to elaborate methods which will recognize intermediate steps of digestion, in the hope of bringing out only specific ferment activities. Whether he succeeds or not, however, it will be difficult to believe that different reactions can be straightway indicative of definite entities as we know them clinically. A new classification will have to be formulated to meet the exigencies of psychiatry.

Treatment of Incoercible Vomiting of Pregnancy.—Jung states that it is difficult to draw the line between

benign and pernicious vomiting of pregnancy, but in his opinion, the involvement of the general health indicates the transition between the two. The scales should be resorted to every three days and loss of weight invoked as the criterion. Much depends upon proper regimen, which should incline to the fluid form, the special articles being chosen by the patient. Drugs are not indicated, for the stomach of the gravida is normal. Suggestion does much better. But if the condition is evidently pernicious the patient must be transferred to a private institution where she will be under strict supervision, and the doctor's orders will be faithfully executed. Such a resource may not be available and in that case the patient must be taken to the clinic where if various measures give no relief the uterus can be emptied. Suggestion may first be tried by utilizing such resources as gastric lavage, nutrient enemata, etc. Patient must be kept in bed, and frequent tests of the urine for acetone may give valuable information because a positive result means that inanition has begun. Fluid food with all possible regard to the due amount of calories should be used; hence milk, cocoa, egg flip are to be given along with broths, mineral waters, and fruit juices. Small, very cold portions should be given. The bowel should be moved by enemata, and nutrient clysters are a recognized part of the treatment. Cracked ice should be pushed for the vomiting, when this is incessant. The mere allusion to the possibility of rectal feeding will often cause cessation of vomiting, showing the suggestibility of these subjects; the same may be true of gastric lavage, and of saline infusion. The institution of fasting days and feeding (milk) days in some sort of rotation has also more or less value. The author, despite his conservative ideals, looks upon hyperemesis as an expression of pregnancy toxicosis, occurring in the suggestible subject. He seems to lay more stress on suggestibility than toxicosis and hence does not empty the uterus until the patient is surely starving. The disease is a matter of the "imponderable" and hence the main therapeutic factors must also come under this same head—physicians and nurses with winning personalities and remedies of suggestive character.

The Medical Profession in Austria.—A correspondent writes to the editor that 900 Austrian physicians have been affected in the present war as follows: 96 have been killed outright, 207 have perished of infectious diseases, 373 have been wounded, and 215 are war prisoners. In Austria the physician is not reckoned among the combatants, but retains his civil status. His activities are largely prophylactic—hence, perhaps, the notable loss from infectious diseases. That the Austrian surgeons do not go to the front like their German colleagues accounts for the low mortality. Among the Germans the actual deaths in battle among the profession may possibly equal the entire disability to the Austrian medical men, if indeed they do not considerably exceed it. In the University of Vienna every effort has been made to advance students of medicine, in order that they may replace units lost in the army. The war has placed many bureau employees, once thought to be superfluous, upon a very different footing. The sanitary personnel is now working overtime. A fear exists that after the war the rank and file of practitioners will be pauperized, partly because they will have lost their clientele; while many a "loaferish moss-back" will retain a comfortable position through bureaucratic rotation. This state of affairs will be even more severe on the young practitioner. The author closes with unstinted praise of the sanitary personnel in the Austrian army and of the medical men who train them.

Book Reviews.

WHO IS INSANE? By STEPHEN SMITH, A.M., M.D., LL.D., Commissioner in Lunacy of the State of New York, 1882-1888. Price \$1.25. New York: The Macmillan Company, 1916.

THIS little volume is a commentary on the experience of the author when, as State Commissioner in Lunacy, he was an official visitor of the institutions for the insane and the Charities and Reformatories of the State. He sets forth in a very simple and entertaining style, entirely devoid of technicalities, the illusory nature of insanity, its origin in the derangement of the functions of the brain cells, the extreme impressionability of these cells, and our power to increase or repress their activity. He takes the stand that our knowledge and treatment of the insane should be based on the teachings of biology and physiology and not alone on metaphysics and psychology. He shows that the insane, contrary to the prevalent impression, are very susceptible to curative measures and that the same principles that are effective in the cure of the insane are applicable to the idiot, the feeble-minded, and the criminal. A plan of organization is suggested by which every person committed to public care should be subjected to an extensive examination by experts in physiology, psychology, and sociology immediately on admission to an institution and it is urged that in dealing with these persons the ideal never to be lost sight of is "cure" and not merely custodial care. Because of his wide experience and ripe judgment the author is peculiarly fitted to present this subject. The book will be not only of interest to the physician, but instructive to the laity, and a most valuable guide at the present time when the need for the education of the public on the prevention of insanity and the possibility of its cure in the early stages has become such a vital problem.

BEAUTY A DUTY. The Art of Keeping Young. By SUSANNA COCROFT, author of "What to Eat and When," "Personal Hygiene," "The Reading of Character Through Bodily Expression," etc. Price \$2.00 net. New York and Chicago: Rand, McNally & Company, 1915.

FOR years the author of this book has been bravely endeavoring to instill into the minds of women the fact that the cultivation of the human face and figure is a duty they owe, not only to themselves, but to the world at large. A broadening and deepening of womanly influence through this means is the reason for this book. Physical culture is used as the road to such success. The book is written in a simple, direct, and attractive style, and goes rather thoroughly into physiological and therapeutic methods for the accomplishment of the desired purpose. It is a pity the author feels it necessary to usurp the function of the physician occasionally. For example: "It [astigmatism] can be corrected by glasses fitted with cylindrical lenses. The difficulty is common, but often outgrown, unless glasses be constantly worn, which makes it chronic." A little later on she gives advice as sound as that just quoted is pernicious: "Ninety per cent. of eye diseases originate from weakness, neglect, or eyestrain. Eye disease should be treated only by specialists." A chapter is devoted to each part of the body and face and head, and, besides directions for improvement, there are a number of "don'ts" at the end of the majority of chapters to warn the woman who would grow careless or indifferent to the care of her physique and mind. "Keep the thoughts pure and the ideals high and every life touched by yours shall respond and be uplifted." Again, "Surely there is an education in the open book of the face as well as on the printed page."

A TEXT BOOK OF CHEMISTRY AND CHEMICAL URANALYSIS FOR NURSES. By HAROLD L. AMOSS, S.B., S.M., M.D., Dr. P. H. Formerly Chemist, Hygienic Laboratory, United States Public Health Service; Physiological Chemist, United States Bureau of Chemistry; Instructor in Physiological Chemistry, George Washington University Medical School, Washington, D. C.; Assistant in Preventive Medicine, Harvard Medical School, Boston, Mass., etc. Price, \$1.50. Philadelphia and New York: Lea & Febiger, 1915.

THE writer of this book believes that the more chemistry a nurse knows the greater is her value to the patient and to the physician; and he further asks—"If the nurse knows no chemistry, how can she be expected always to remember that starches yield sugars and are to be given to the diabetic with extreme caution? And

what can the term calorie mean to her?" So far as we have been able to ascertain, the present volume (which is neither better nor worse than other works of the kind) will not help the nurse to obtain any meaning of the term calorie; and while the book contains a certain amount of information on some of the chemical elements and compounds, it provides very little help towards an understanding of general chemical principles. More space is given to the consideration of the diazonium compounds and the quantitative estimation of dextrose (both somewhat advanced topics) than to an explanation of such terms as acid, base, and salt.

EMERGENCY SURGERY. By JOHN W. SLUSS, A.M., M.D. Associate Professor of Surgery, Indiana University School of Medicine; Ex-Superintendent Indianapolis City Hospital; Surgeon to the City Hospital. Third Edition, Revised and Enlarged, with 685 Illustrations, some of which are printed in colors. 12mo, 832 pages. Flexible leather, gilt edges, round corners. Price, \$4 net. Philadelphia: P. Blakiston's Son & Co., 1915.

THIS book was designed to meet the needs of the general practitioner who may be called upon to deal with emergency cases requiring surgery. In the initial chapter entitled: "The general practitioner as an emergency surgeon; his duties and responsibility," the author clearly indicates his views as to the duty of the practitioner to be prepared not only through knowledge of the technique of emergency operations, but by having his emergency kit ready for use at any moment. In our opinion, comparatively few general practitioners who operate only "in an emergency" are likely to be qualified to do more than intelligently *advise* the performance of a great many of the operations described in this book. Outside of this remark we have nothing but praise for this work; for if the general practitioner will prepare himself in advance by learning what Sluss has to say as to diagnosis and the indications for surgical intervention, and has sufficient manual dexterity to carry out the operations as they are advised and described, his results should be as good as could well be expected under the circumstances.

This book seems worthy of forming part of the equipment of any practitioner who lives at a distance from a surgical center or a competent surgical specialist; for it covers the field of emergency surgery remarkably well and the advice for handling emergency cases is almost uniformly sound. Mechanically, the book is well printed, the illustrations are good and to the point, and with the flexible leather binding the book is well suited for packing with the emergency outfit which Sluss insists such a practitioner should always have ready.

TRANSACTIONS OF THE TRI-STATE MEDICAL ASSOCIATION OF THE CAROLINAS AND VIRGINIA. Seventeenth Annual Session held at Charleston, S. C. February 17 and 18, 1915.

THE book contains the transactions of the Tri-State Association of the Carolinas and Virginia including a series of papers read at the meeting, all of them of interest and some of them exceptionally so. The president, Dr. E. C. Register, delivered an able address and a great deal of credit is due to him for the success of the meeting. The book containing so many interesting papers should be useful for reference.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc. Edited by HENRY W. CATTELL, A.M., M.D. Vol. IV, Twenty-fifth Series, 1915. Price, \$2.00. Philadelphia and London: J. B. Lippincott Company.

THIS volume marks the end of twenty-five years of existence for the International Clinics, and is its one hundredth number. It contains twenty-two articles, of which five have to do with the progress of some of the branches of medicine during the past quarter century. One by William Osler is very flattering to this country, and we could wish that it were better deserved. Probably the most important contribution is the Alvarenga Prize Essay by J. E. Sweet on "The Surgery of the Pancreas." There are several other interesting articles. A brief note by the editor summarizes the history and accomplishments of this publication, and announces his retirement and the appointment of Dr. Henry R. M. Landis of Philadelphia as his successor. The "Clinics" have had a long and honorable, as well as useful, existence, and one may predict that their prosperity will continue under the guidance of their new editor.

Society Reports.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, January 5, 1916.

THE PRESIDENT, DR. JAMES C. WILSON, IN THE CHAIR.

Operation for Removing the Gall-Bladder.—Dr. JOHN B. DEEVER described his technique in this operation, claiming that it allowed exploration of the common duct in its entirety and control of bleeding from the gall-bladder bed. With the abdomen open, the gall-bladder and the right free border of the gastrohepatic omentum freed of any adhesions, the region was thoroughly walled off, the wound being kept wide open. The edge of the liver and the fundus of the gall-bladder were grasped with the left hand carrying a piece of moist gauze, pulled downward, outward, and upward, making taut the cystic duct and the free border of the gastrohepatic omentum. In the presence of a diverticulum or adherence of the liver to the parietal peritoneum, the cystic duct and the free border of the gastrohepatic omentum were made prominent by grasping the diverticulum with a pair of long curved forceps and making traction. When the diverticulum was adherent to the free border of the gastrohepatic omentum it was to be freed before effective traction could be made upon the cystic duct. A small incision was made through the upper part of the free border of the gastrohepatic omentum and the upper end of the common and cystic ducts exposed. A small piece of gauze was placed beneath the border of the gastrohepatic omentum to take up the bile escaping upon division of the cystic duct. The cystic duct at its junction with the gall-bladder was clamped with a pair of long hemostatic forceps and cut across distal to the forceps with the actual cautery. A small, followed by a larger, probe was passed into the stump of the open cystic duct and carried through the common duct into the duodenum, in this wise determining whether the duct and the papilla of Vater were patulous. With the probe still in the common duct, palpation was made to determine the presence of stone, or obstruction outside of the duct. The cystic artery was clamped and cut. If not necessary to drain the common through the stump of the cystic duct, the cystic duct was ligated and next the cystic artery. The next step in the operation, the separation of the gall-bladder from the liver, was made by a dissection from below upward. The gall-bladder was freed and turned upward and outward and the gall-bladder bed closed, carrying a continuous catgut suture through the liver substance forming the sides and floor of the gall-bladder bed. The free end of the suture was left long and tied to the portion of the suture carried by the needle through the liver substance. The tie was made on the upper side of the line of apposition of the walls of the gall-bladder bed. It was pointed out that as the gall-bladder was removed step by step the suture was passed and tied so that when the gall-bladder was entirely removed, the gall-bladder bed was completely closed, making the procedure bloodless, which to Dr. Deever's mind was far preferable to packing the gall-bladder bed with gauze or placing a cigarette drain retained by suture. The next step was that of suturing the divided layers of the gastrohepatic omentum, but not covering in the stump of the cystic duct, and the final step was the placing of a small rubber tube down to and just beyond the free border of the gastrohepatic omentum. This tube was to be retained for four or five days to provide an exit for the bile in the event of the giving way of the ligature on the cystic duct. When prolonged drainage of the common duct was necessary Dr. Deever opened it and inserted a T-shaped rubber drainage tube. He stated that one patient under Dr. Riesman's and his care had been wearing such a tube for more than two years. Dr. Deever believed that early drainage of the common duct by this method or by a cholecystoduodenostomy to be the only chance for the cure of pancreatic diabetes.

Dr. A. P. C. ASHHURST asked Dr. Deever what he did in the more troublesome cases than the ones illustrated, and which incision of the abdominal wall best exposed the whole biliary tract. The bayonette incision of Kehr, he said, was used for years on the continent of Europe, and Terrier had come to use it because he had found the Mayo Robson incision to be insufficient. He noted that Dr. Deever had said nothing about empty-

ing the gall-bladder. If this were very large Dr. Ashhurst pointed out that the cystic duct and the gastrohepatic omentum could not be reached until it was emptied. Another point in technique was that if the patient were short and fat the cystic duct when divided would retract at the distal end. It had been his experience to have the tube pull out of the common duct during operation and to have difficulty in again isolating the duct and replacing the tube. In the method described by Dr. Deever there was no way by which one could hang on to the end of the cystic duct after dividing it. Dr. Deever, he said, had described the typical operation which did not take account of the *atypical* cases. His only criticism was that in the surgery of the biliary tract the difficult cases were so very frequent that they merited recognition.

Dr. DEEVER, in answering Dr. Ashhurst, admitted that some cases were more difficult than others, yet he had always been able to carry out the technique described. Occasionally he aspirated as well as freely opened the gall-bladder to empty it. Adhesions presented the most troublesome complication. The straight incision through the rectus muscle was the one he most commonly used, although occasionally using the Mayo Robson incision.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 14, 1915.

Dr. WALTER LESTER CARR IN THE CHAIR.

Hypertrophic Pulmonary Arthropathy in a Girl of Eleven Years.—Dr. CHARLES HERRMAN presented this patient. Her family history was negative. She was one of eight children, none of whom had died, and the mother had had no miscarriages or still births. None of the other children had any symptoms pointing to tuberculosis of the lungs, bones, or lymph nodes. When this patient was seven years of age the mother noticed that she held her head to one side and later the spinal curvature became more distinct. In 1912, when eight years of age, the patient was operated on by Dr. Whitman at the Hospital for Ruptured and Crippled. During the past four years she had lost weight and had a cough which was worse at night, but no sweats. The enlargement of the fingers began about seven months ago and that of the knees and ankles about four months ago. There had been occasional slight pain in the knees, ankles, and fingers. The patient was admitted to the Lebanon Hospital September 1, 1915, at which time she weighed 49 pounds, was poorly nourished, had marked spinal curvature, pronounced deformity of the chest and dyspnea, more marked after slight exertion. Examination of the lungs showed râles in the axillary line and over both bases posteriorly. The patient complained of pain on both sides of the chest. There was a small amount of purulent expectoration, which on examination failed to show the tubercle bacillus. There was distinct atrophy of the muscles of the upper arm, and the leg, the hands were cold but not cyanotic, and the ends of the fingers and toes were clubbed. The patient's temperature ranged between 99° and 101.2° F. The urine contained a small amount of albumin, but no casts. Dr. Herrman exhibited radiographs of the hands showing in the metacarpal bones a thin layer of new-formed bone under the periosteum and a similar but less distinct layer in the first phalanges. Similar changes were shown in the bones of the feet. The radiograms of the knee showed layers of new formed bone over the upper end of the tibia. The joint itself presented no changes. Dr. Herrman said that about 100 typical cases of hypertrophic pulmonary osteoarthropathy had been reported, only seven of which had occurred in children. In adults the condition occurred five times as often in males as in females, and most of the patients were between twenty and forty years of age. Some form of chronic disease of the lungs was present in 75 per cent. of the cases, the most frequent lesion being bronchiectasis and next in frequency was chronic pulmonary tuberculosis and empyema. The condition was occasionally seen in diseases of the liver. One of the most plausible explanations of the changes in the bone and the tissues surrounding the joints was that the imperfect function of the lungs caused a lack of proper elimination of toxic substances. The characteristic feature of the condition was the deposit of new bone under the periosteum of certain bones. The enlargement of the joints was due to hyper-

trophy of the soft tissues covering the terminal phalanges, and not to any change in the cartilage. The clubbing of the fingers was also due to hypertrophy of the soft tissues and not to any change in the bone itself. In extreme cases the nails became convex and curled at the end.

Dr. HENRY W. BERG asked Dr. Herrman whether the patient had had a Wassermann reaction taken and whether it was negative or positive. He said he did not remember having seen more than two such cases and did not know there had been such a large number of cases reported as Dr. Herrman had stated. One of his cases exhibited a spinal arthropathy somewhat similar to those of locomotor ataxia. The x-ray did not show a bone disease process. The rapid collapse of the spine through destruction of the bodies of the vertebræ was not what one usually saw in Pott's disease, but was rather suggestive of the possibility of specific disease. The slight amount of paralysis indicated that the collapse had occurred so suddenly as to cause compression of the cord.

Dr. CHARLES HERRMAN, in reply to Dr. Berg's question with reference to the Wassermann reaction, said that the test had been made and was negative; the von Pirquet, however, was positive. The lungs had been fluoroscoped, but on account of the deformity of the chest one could not state definitely that tuberculosis was present. There were no signs of specific disease in the parents or children and besides there was positive evidence of tuberculous infection and it was known that chronic pulmonary tuberculosis was very frequently present in the history of the condition.

A Case of Meningitis with Complete Recovery.—Dr. W. MORGAN HARTSHORN presented this patient, a child 2½ years old, who had been admitted to Roosevelt Hospital with the symptoms of meningitis. There was nothing of significance in the previous history of the child. The present illness began with the vomiting of green watery fluid, spasms, and later general convulsive movements. At the time of admission to the hospital the child was unconscious, eyes staring, and the right pupil larger than the left. There were furuncles on the knee, and pustules on the gluteal region, some of which were covered with a thick crust. The heart was rapid and crepitant râles were heard in the chest. There was slight opisthotonos, but no Kernig, Babinski, or Oppenheim signs, or ankle clonus. A diagnosis was made of meningitis complicated by bronchial pneumonia. A lumbar puncture was performed and examination of the fluid showed that most of the cells were lymphocytes which was unusual and very puzzling. The patient's temperature during the first week in the hospital ranged from 100° to 104° F. and the pulse between 96 and 120. The child remained in an unconscious condition. During the second week the temperature ranged from 101° to 106° F., pulse from 120 to 150. Very little spinal fluid was obtained by puncture, but it was still purulent. The child's pulse grew weaker and its condition was considered hopeless. During the third week the temperature continued to run high, from 103° to 100° F., and the pulse ran from 99 to 145. At this time they obtained 25 c.c. of clear spinal fluid. They had given very little medication, a little whiskey when the child was refusing nourishment, a few bromides, and a little urotropin. The temperature then began to come down, though the child was still unconscious. It continued to fall and the child began to take nourishment and to show signs of intelligence. The symptoms gradually disappeared and the patient went on to recovery and was discharged in good condition.

Dr. L. E. LA FETRA said that cases of epidemic meningitis even in young children frequently recovered without treatment. He related an instance occurring in a child 14 months old, in which thick pus was withdrawn and complete recovery had taken place. In the case reported the findings were rather peculiar in that the majority of the cells were said to be lymphocytes, but the high temperature and the blood count would have indicated the case to be one of meningococcus meningitis. Dr. LeFetra said it was his custom to administer the anti-meningitis serum whenever he found a cloudy spinal fluid without waiting for a complete examination. One should make it a rule never to inject more serum than the amount of spinal fluid withdrawn. A house surgeon might inject 20 c.c. for the first dose and follow it by similar doses, even though less spinal fluid was withdrawn. Such a procedure had been followed by prompt respiratory failure and death. A good rule to follow was not to give of the serum more than two-thirds the volume of spinal fluid withdrawn.

In some cases it might be very difficult to withdraw fluid and in these it might be necessary to puncture the ventricles and make the injection directly into them.

Case of a Child Swallowing a Foreign Body.—Dr. W. MORGAN HARTSHORN presented this child, 18 months old, who had swallowed a safety pin on July 26. Radiographs were taken, but gave no indication as to the location of the safety pin. The child had diarrhea and was irritable for ten days or two weeks, and was then discharged from the hospital. Nothing was heard from it until October 15, nearly three months after it had swallowed the safety pin, when the mother reported that the child had passed the safety pin.

Scarlatina: Some Unusual and Severe Types.—Dr. HENRY W. BERG presented this communication, in which he said that the ten minutes allotted to him allowed him only to present a schematic arrangement of the types of severe cases of scarlet fever, such as one saw in large contagious disease hospitals. The first group which he considered were the severe toxic cases. This group had certain characteristics and a very uncertain prognosis. There was either a very severe eruption, or there might be no eruption except around the neck. There was a very high temperature persistently maintained without any attempt at resolution. The rash was punctate and almost blue. The punctate spots were sometimes almost purple, but on compression became white. These cases must be differentiated from the hemorrhagic cases. These never got well while the toxic non-hemorrhagic cases might get well. All the severe toxic cases had cerebral symptoms of a marked kind, resembling meningitis, but one did not get the Kernig, the Babinski, or other physical signs characteristic of meningitis, but one might get coma. As far as the kidneys were concerned one might find albumin, but rarely casts, except in the toxic hemorrhagic cases. Of the cases of the severe toxic type a few had a slight amount of adenitis, usually marked angina, and an eruption of the congested punctate type. There was a type of severe cases that might be designated the septic type. Physicians frequently confused this type of severe scarlatina with the toxic type. The septic type was a severe scarlatina plus the results of a mixed infection with the pus organisms. These were usually the cases with the severe throat complications and diphtheritic and septic types of anginas. In the septic cases there was rarely more than one attack of vomiting, whereas in the toxic cases the vomiting was more persistent. The temperature of septic scarlatina had practically the features of the temperature curve due to septic infection. One of the most important symptoms was the enlargement of the glands at the angle of the jaw. All the glands in that region might become involved. These cases became extremely ill with the angina, some of which might be diphtheritic, and they invariably showed albumin in the urine. The importance of differentiating the septic from the severe toxic type was obvious if only because the cases of the toxic type had a very bad prognosis, while in the septic type the prognosis was better. The sepsis might be due to different organisms or combinations of organisms, but the streptococcus had been recognized as the chief cause of the sepsis in three-fourths of the cases. Not all the cases called hemorrhagic scarlatina by clinicians really belonged to the hemorrhagic type. The true hemorrhagic cases were invariably fatal. This type of severe scarlet fever showed petechial spots and hemorrhages from the nose, ears, throat, intestines, kidneys, or other organs. The finding of a few hemorrhagic spots did not constitute a true hemorrhagic scarlatina. The peliosis rheumatica accompanying scarlatina might cause such cases to be diagnosticated as hemorrhagic scarlatina. The so-called scarlatina complicating burns, surgical injuries, and puerperal fever were, in the opinion of the speaker, none of them scarlet fever. In the cases of so-called scarlet fever complicating the above conditions the eruption was not typically punctate, the throat symptoms were rarely characteristic, there was not the universal lymph adenitis, and the desquamation was not the typical scarlatinal desquamation. The scarlatinaform eruption in these cases was a punctate erythema manifesting itself as a symptom of sepsis.

Scarlatina: Morbidity and Case Fatality, by Locality, Sex, Age, and Season (Based on a Study of over a Million Cases).—Dr. HENRY H. DONNALLY of Washington, D. C., presented this paper. He stated that such questions as "Could the differences in family and individual susceptibility to scarlet fever account for the differences in fatality between different small epidemics to the

disease?" "Would it be found that after all scarlet fever was a pretty uniform disease, attacking year in and year out an average number of children, of whom an average number could be regularly expected to die in a fairly uniform proportion?" and similar questions had been suggested to him by Dr. Howland. Starting out with the reportable diseases, he had found that scarlet fever was the only one that admitted of such investigation with any satisfaction because it had been well reported and had undergone little change in the method of treatment and also because it could usually be readily diagnosed. Of course, the value of such a study depended upon the completeness with which cases of scarlet fever were reported. Very mild cases were frequently unrecognized and very severe ones died without scarlet fever having been given as the cause of death. These two types balanced up more or less, so that it was believed the fatality figures obtained for this study gave an approximately accurate idea of true conditions. In the course of this study something more than seven million cases had been collected, but only those were retained where it was believed that approximately all cases and deaths were reported. Among approximately 2,000,000 cases there were 104,500 deaths, a case fatality of 5.25 per cent., while the morbidity rate was 3.9. This meant that about four persons in every 1000 inhabitants had scarlet fever and one case in twenty died. A study of a large number of cities for different periods of time showed that there was a marked difference in the amount of scarlet fever in different localities. In large cities the disease might be abundant in some parts and slight or absent in others; the case fatality was also higher in some places than in others. England had more scarlet fever than any other place studied. Since 1892 the mean case fatality of England and Wales was 3.3 per cent., and of the Russian Empire 22.3 per cent. For the past forty years that of former New York was 12.2 per cent, Brooklyn 11 per cent, Boston 7.2 and Christiania 9 per cent, while Norway as a whole gave 7.9 per cent. In all the places studied it was found that scarlet fever was practically endemic. The fluctuations in the amount as evidenced by the annual morbidity rates followed no rule as regarded periodicity. An epidemic either subsided slowly during two or three years or might attain a greater height in its second than in its first year. It went slowly or came slowly, as compared with measles. There might be but a single year between epidemics of scarlet fever, or there might be two, three, four, five, or more years, with low morbidity rates between them. There had been no striking reduction in the annual morbidity rates anywhere during the periods studied. They fluctuated from year to year within essentially the same limits now as years ago. The smaller the place the greater were the annual fluctuations in morbidity rates. The amount of scarlet fever showed a tendency to decline in Norway and Philadelphia, while in the Russian Empire and in Montreal the tendency was in the opposite direction. There had been a consistent, general, and marked reduction in the case fatality during the past half century, and that in the absence of specific treatment. In contrast to this general rule, the later case fatality in the Russian Empire had been around 30 per cent., while twenty years ago it was only half that amount. In Australia and New Zealand there had been very low morbidity rates and a case fatality of only 1.5 per cent. The explanation of the lowered case fatality seemed to be that the disease was milder to-day than formerly, though the removal of patients to hospitals had improved the care given them, and it was possible that the practice of administering diphtheria antitoxin to all scarlet fever patients brought into hospitals might also be a factor, since combined scarlet fever and diphtheria had a high case fatality. It was also conceivable that the immunity had been increasing during the three hundred years since the disease was first recognized. The study of seasonal influences showed that the height of an epidemic might occur at any season of the year. January and December usually had the maximum number of cases and August and September the smallest. Case fatality was highest in the summer months and lowest in the fall. A study of sex susceptibility showed that the number of male cases of scarlet fever bore almost the same ratio to the number of female cases that the number of males bore to the number of females in the entire population. There seemed, however, to be a slightly increased susceptibility of the males. During the first five years of life males were more susceptible while between five and fifteen years females were dis-

tinctly more susceptible. The number of deaths from the disease was both absolutely and relatively greater among males than among females at each age period throughout life. Nearly one-half the cases of scarlet fever occurred in children under the age of seven years, the percentage being about 10 per cent. for each of the years. Somewhat over 1 per cent. occurred under one year of age. Few adults, though exposed, became infected. The disease was most fatal during infancy. Ninety per cent. of the deaths occurred under ten years of age.

Scarlatina: Prevention and Control of Scarlet Fever in New York City.—Dr. S. DANA HUBBARD read this paper. He said that in discussing the "control" of scarlet fever in New York there was no such thing as "controlling" scarlet fever. The control of scarlet fever had presented many peculiar and vexatious problems, and especially when, prior to the modification of the regulations, the Department of Health failed to receive the support of both physicians and infected families. By the time the diagnosis of scarlet fever had been made, frequently a number of exposures had taken place and particularly was this true when the patient became ill in school or in a public conveyance. Parents and teachers should be taught that a child vomiting suddenly and without apparent reason was a danger to others. When vomiting was accompanied by a fever and rash a physician should be called, the patient properly isolated, and the places occupied during the onset of the disease should be carefully cleaned and disinfected. All persons should be taught that vomited material was very infectious and a danger to the community. A study of later (secondary) cases both in New York and in Chicago had proved that where there was a close regard for regulations of quarantine there were the fewest secondary cases. The freedom from scarlet fever of the Italian colonies of the city was interesting and might be due to the fact that in a mild form of the disease the families did not consult a physician. Quarantine as formerly practised by the Department of Health did not seem to meet with approval and support, and a modification was made substituting trained nurses for the medical inspectors. These nurses were trained in the duties of establishing and maintaining quarantine. The nurse visited the case, instructed the family, saw that the patient was comfortable, and did whatever social welfare or uplift work was necessary. This change to nurses had been highly successful. Dr. Hubbard presented a table of incidence and mortality of scarlet fever in New York City for the past six years. The figures showed that the fatality had varied from 6 to 4 per cent.; it was 4 per cent. at present. Particularly was it interesting to note the experience in Queens, where, in 1912, there were only six deaths from scarlet fever, which was followed in the two succeeding years by a large increase, 46 in 1913 and 40 in 1914. They had been unable to explain this. Exposures to scarlet fever in schools were most interesting. Mild cases, difficult of determination, and other cases unrecognized no doubt were the source of many infections in the schools. The remedy for school infection must be sought in greater alertness on the part of school inspectors to detect the presence of infection. They should especially be on the watch for mild cases and in addition teachers and mothers should be educated to recognize the early cardinal symptoms of scarlet fever. Dr. Hubbard described the present system of control of infectious diseases in New York City and stated that the principles of control consisted in regarding the patient as the original source of infection and in concentrating all efforts here. The most frequent carriers of infection were the patient, persons coming in contact with the patient, and the patient's surroundings, the bedding, room, clothing, etc. This being accepted control must be exercised by safe and sane quarantine continued until every possible danger signal was passed both for the patient and for the public. The quarantine to be effective must be wholly efficient. Here cooperation of all concerned was the keynote and no hard and fast rules were applied in any case. Convalescence was supervised and the patient afforded every opportunity to a safe and speedy recovery. Poverty and ignorance were their greatest opponents. Remove these and rigid quarantine could be exercised with positive prevention of sickness and the saving of many lives. Men and money were often inadequate but intelligent application of means and knowledge available would result in appreciable and effective control.

Dr. HAVEN EMERSON said that Dr. Donnally's paper put the matter before health officers in rather a bad light. In communities in which the death rate seemed

high it usually meant a failure to report cases and that there was a lack of an effective method of impressing on the community the necessity of reporting cases. Health officers did not feel so hopeless regarding the situation as the statistics presented might lead one to assume. A number of outbreaks of scarlet fever had been traced to the milk supply. Pasteurization of the milk supply seemed to have some bearing in decreasing the number of cases of scarlet fever and also the number of cases of septic sore throat and even of tonsillitis. From 1868 to 1877 the death rate from scarlet fever in New York was 91 per 100,000 while from 1908 to 1912 it was but 18 per 100,000, a reduction of 80 per cent. and there had been a further fall in the case rate and mortality since 1912. Dr. Emerson said it was not fair to check off mild undiagnosed cases against severe undiagnosed fatal cases, since there was no evidence to show how they would balance one another. In Poughkeepsie where they recently had an epidemic, so-called, of septic sore throat, physicians, after having had their attention called to the matter, admitted that many of the cases might have been cases of scarlet fever. The Health Department was now using a system of recording non-susceptibles. When an instance of infectious disease was reported and the diagnosis verified, the patient was given a certificate stating that he or she had had that disease and might be regarded as immune. In this way there was an increasing number of children whose attendance at school was not interfered with because of a case of that particular disease in the same house provided the patient could be properly isolated and watched.

Dr. MEYER SOLIS-COHEN of Philadelphia said that if it was true that they were making no progress in the control of scarlet fever, as Dr. Hubbard stated, it behooved them to find out why the disease was always present. He took exception to Dr. Donnally's statement that the unreported cases balanced those dying without the disease being recognized; he thought the unreported cases were far in excess of those dying without scarlet fever being recognized as the cause of death. Dr. Solis-Cohen cited a number of instances showing the prevalence of unrecognized cases in Philadelphia. One should watch for these mild cases of scarlet fever and should be especially alert to detect them during an epidemic of measles or German measles, for it was at such times that they were likely to pass unrecognized. The remedy for the scarlet fever prevalence was to be found in the recognition and control of the mild cases of scarlet fever and this could be brought about by popular education, as Dr. Hubbard had suggested, but not so much as to isolation and quarantine as to the danger of mild unrecognized cases and how to recognize them. Many of these cases might be reached through the school. Only the medical inspector should not wait until two or three cases had developed before examining the school, but, after the first case, should make an inspection of every child in the school and then keep on going through the school until the period of incubation had passed since the finding of the last case. He must go even further and examine every school child on its return to school after having recovered from ivy-poisoning, measles, German measles, etc., for there was the possibility that these might have been scarlet fever. Since mild cases of scarlet fever frequently did not have a physician there should be a law compelling the householder to report cases of contagion occurring in his house, especially if there was no physician in attendance. Physicians who failed to report their cases should be prosecuted. To allow a man to make a practice of not reporting cases was unfair to the honest physician. Children absent from school for an unknown cause should be investigated by an attendance officer, who should report cases of illness in absent children or members of their families.

Dr. W. L. SOMERSET said he did not wish to differ from Dr. Berg concerning the hemorrhages in the eruption but to add that certainly in scarlet fever petechiae or small hemorrhagic areas were not necessarily rheumatic and did not have a perceptible effect on the clinical course of the disease. The discovery of the Klebs-Loeffler bacillus and the control of diphtheria by antitoxin might have had a marked effect on the morbidity and mortality of scarlet fever since the two diseases frequently occurred together. Since it was customary to give an immunizing dose of antitoxin to every scarlet fever patient entering a hospital there were fewer instances of this complication. Dr. Donnally said that statistics showed that something more than 1 per cent. of the cases of scarlet fever occurred in infants under

one year of age; it had been his impression that a very small fraction of 1 per cent. occurred at this early age. In reference to the confusion of scarlet fever with milk-borne sore throat, Dr. Somerset made the point that one could not safely make a diagnosis of scarlatina sine eruptione.

Dr. LOUIS CURTIS AGER of Brooklyn spoke of the different ideas that different individuals might get from the same statistics. It was stated that Old New York had a high mortality rate in comparison with the morbidity rate and Dr. Donnally attributed this to locality, but why would it not be more reasonable to say that the high mortality was due to laxity in reporting cases? It had been stated also that the morbidity rate was unchanged; but it was just as reasonable to say that as a result of education the number of cases had been greatly reduced while the percentage of cases reported was much greater than formerly; so that in reality, Dr. Ager said, there was now a lower morbidity rate than formerly and we were making gratifying progress in controlling the disease.

Dr. HENRY HEIMAN said that as to the albumin in the urine, that might be found in any infectious disease; the point with reference to scarlet fever was that albuminuria occurred about the third week of the disease. Shortening the period of quarantine had its advantages in that with the shorter period one was more likely to get the cooperation of the families, and it might also be suggested that a physician, after attending a case of scarlet fever, might do his part in preventing the spread of the disease by washing his hands, spraying his nose, and gargling his throat. Some of the mild cases of scarlet fever were extremely difficult to diagnose, and in certain instances Dr. Heiman said he did not believe any one could do it.

Dr. HENRY W. BERG congratulated Dr. Donnally on the amount of information he had collected and stated that a man who merely heard the paper once did not grasp immediately the large amount of information it contained. It contained a great deal that would aid in prognosis and the figures spoke for the utility of health department work. The paper showed, Dr. Berg said, that the statistical returns from Russia were very much more reliable than was generally supposed and it also showed that a much larger number of cases were reported in proportion to the population in Russia than in some of our large cities.

Dr. DONNALLY, in closing, said he had not claimed that the fatality figures were strictly accurate and did not believe that they were, but they were probably approximately so, and gave a fair idea of conditions. The point brought out by Dr. Emerson that deductions from combined groups of cases were fallacious was well taken, but it was interesting to get the figures roughly from such a large combination. He did not believe that all the cases reported in children under one year of age were actually cases of scarlet fever, but one could not go back of the figures as presented in the health office reports.

Dr. S. DANA HUBBARD, closing the discussion, said that there was a law requiring doctors, superintendents and managers of hospitals to report cases of scarlet fever as well as cases suspected of having this disease; there was also a law requiring every person having knowledge of the existence of a communicable disease to report the fact to the Department of Health. In the latter instance the difficulty of enforcing the ordinance was in the fact that it was difficult to obtain evidence of knowledge of the fact—that but few laymen knew what scarlet fever was when they saw it. With reference to the element of time in the quarantine of scarlet fever, it was appreciated that thirty days minimum period was an arbitrary period pure and simple. The Department had no method of determining the period of infectivity in scarlet fever and so had to accept the opinion of its medical advisers. In measles the work of Bordet and Gengou, later supplemented by Anderson and Goldberger, had enabled the Department to eliminate fourteen days in that disease and substitute a minimum period of five days. Dr. Hubbard added that, according to the custom of the Health Department, if any physician believed the quarantine period of thirty days required as a general rule in all cases of scarlet fever was unnecessary and inflicted in certain instances a hardship or was detrimental to the patient, if he would bring the matter to the attention of the Department, giving all facts, the case would receive careful consideration and, if it was safe to do so, it would be discharged on its own merits, as the facts warranted.

SECTION ON SURGERY.

Stated Meeting, Held November 5, 1915.

DR. JOHN DOUGLAS, SECRETARY, IN THE CHAIR.

Impacted Vesical Calculus.—Dr. CHARLES GOODMAN presented a man, fifty-six years of age, whom he first saw April 17 last. He had had attacks of pain referable to the left kidney; this had occurred off and on for twelve years. For several days past, attempts to pass urine was accompanied with a great deal of pain in the bladder. It was followed by complete retention. His physician attempted catheterization but failed to enter the bladder; this operation was followed by a most profuse hemorrhage from the urethra and Dr. Goodman was then called to see him. He found the patient prostrated and in great agony; he was bleeding profusely from his urethra and seemed to be suffering great pain referable to the bladder. His urine had not been voided in twenty-four hours and the bladder extended above the umbilicus. Dr. Goodman succeeded in passing a catheter and relieved him of about 30 ounces of very bloody urine. This was followed by considerable relief of the pain but, in view of the profuse hemorrhage which persisted after the catheterization, he suggested that the patient be removed to the hospital with the view of exposing possibly, a neoplasm in the bladder. While the presence of calculus was thought of, he did not believe that its presence was sufficient to account for this profuse and continued hemorrhage. After admission to the hospital the bladder was opened by Dr. Goodman under local anesthesia and he came upon the large calculus which he presented to the Section; this was imbedded in the bladder and in order to dislodge it and favor its delivery through the bladder opening, which had become contracted around the calculus, the patient was given nitrous oxide gas and the calculus was then delivered with a placental forceps. The bleeding from the extensive eroded mucous membrane of the bladder was controlled by hot irrigations. A drainage tube was inserted and the upper part of the wound was sutured. The calculus weighed $5\frac{1}{4}$ ounces and was faceted corresponding to the surface of the lobes of the prostate and a projection which apparently protruded into the prostatic urethra. About three weeks after the operation, the patient developed prostatic abscess of the left lobe which was drained through a perineal incision. The wound in the bladder, as well as in the perineum, entirely healed and, with the exception of a small amount of residual urine, which required occasional irrigation of the bladder, the patient had been in good health, gained about 30 pounds, and was able to attend to his business. The case was presented on account of the unusual size of the calculus and on account of the extraordinary amount of hemorrhage caused by the calculus; this was due to the fact that the calculus had become firmly imbedded at the base of the bladder, and its attempted dislodgement during attempts of catheterization was sufficient to produce shock due to hemorrhage. A radiograph taken of the kidney did not reveal any calculi, although the patient had volunteered the information that he had been able to collect about sixteen small calculi, passed at intervals, during the last twelve years. A radiograph was not taken before the operation because the patient was admitted in a condition where temporizing was not considered advisable.

Veno-Peritoneostomy for Ascites.—Dr. CHARLES GOODMAN presented this case as an example of reconstructive or reparative surgery. The woman had been a great sufferer with dyspnea and very frequent asthmatic attacks of the most severe type which was due to cardiac disease. The heart was very much hypertrophied and almost filled the left side of the thorax. She had ascites and the circumference of her waist measured 46 inches. They decided to give her the benefit of Freund's operation in order to relieve the rigid state of her emphysematous thorax. Therefore, they removed the 2nd, 3rd, 4th and 5th costal cartilages and performed a plastic operation by reflecting the anterior and posterior layers of the perichondrium respectively over either severed end of the cartilage in order to produce a permanent joint, permitting free mobility of the ribs. Her dyspnea was relieved and the asthmatic attacks were decidedly diminished in frequency. About six months later they performed a veno-peritoneostomy. Her ascites was causing her a great deal of distress and in order to relieve her of this distention, the right saphenous vein was exposed for a distance of about 4 inches and tunnelling the

skin from this incision up to the lower part of the abdomen, the peritoneum was opened through a small incision, and the split end of the saphenous vein was sutured to the parietal peritoneum. The omentum which presented was fixed by two sutures to the parietal peritoneum a short distance from the anastomosis in order to prevent its interference with the drainage of the vein. The wounds were closed. This operation was first suggested by Ruotte, the idea being to establish a permanent communication between the peritoneal cavity and the venous system. In inverting the vein, hemorrhage was prevented by the valves which only permitted the fluid to travel in one direction, namely, downward from the peritoneal cavity to the femoral vein. In this case, the circumference of the abdomen was reduced 10 inches and remained so up to the present time. Should the amount of fluid in the abdomen increase, they might repeat the operation on the opposite limb. The technique of this operation had been offered as a possible substitute for anastomosis of the portal and hepatic veins, or the establishment of a fistula—an operation perfectly feasible in a dog, but one that entailed almost unsurmountable difficulties in the human being. The operation was perfectly feasible under local anesthesia.

Dr. ROBERT T. MORRIS said that there was one point that would stand in the way of success of the operation, the question of the hydrostatic balance; he had been struck by this fact in his operations on hydrocephalic cases, in which the temporal vein was connected with the lateral ventricle. The vein did not carry off the fluid from the ventricle. This same difficulty might be encountered in the operation devised for the relief of ascites. There was still another factor which stood in the way of success, the tendency to the formation of lymph exudate, such as occurred in all work disturbing the endothelium of the veins. This exudate had a tendency to plug the lumen of any blood-vessel. These two factors might stand in the way of success, but he hoped that this was only a theoretical objection to the operation rather than a matter of fact.

Dr. JOHN DOUGLAS asked Dr. Goodman how large were the veins he had to deal with. He recalled one operation he did where the saphenous vein was so small that the operation was unsuccessful.

Dr. CHARLES GOODMAN replied that the vessels he dealt with were about one-half the diameter of an ordinary lead pencil. He split the end and employed the method commonly used in implanting the ureter into the bladder. The objections to the operation were purely theoretical rather than practical as the report of his case had proven. After a period of six months the abdomen had remained flat. He believed that a great deal of the success of these operations depended upon how one handled the vein. Arteries and veins must be handled with great care so as not to injure the intima and it must be emphasized that the operative field should be absolutely free from blood.

Operation for Malunion of Fracture of Head of Radius.—Dr. SETH M. MILLIKEN presented this case. The patient, a man thirty-four years of age, an iron worker, was admitted to the Lincoln Hospital on September 28, 1915, and was operated upon by him September 30. An incision was made from just above the olecranon and over the external epicondyle downward about 2 inches on the flexed forearm over the bony prominence of the fracture. The incision was deepened into the elbow joint. No obstruction could be made out between the radius and ulna and humerus. The displaced fragment was removed with the chisel. This did not release the joint. The upper end of the radius was then stripped of cartilaginous and muscular attachments dividing the orbicular ligament on the outer side. Separation could not be effected between the radius and the lesser sigmoid. The Gigley saw was passed as deeply as possible and the upper fragment removed but this did not remove the entire head, but gave room to pass a carrier around the neck of the radius, so that the remainder of the head could be removed with Gigley saw. This was done and pronation and supination could then be carried out to almost the full extent. Extension was limited by contractions and adhesions in the anterior surface of the capsule which were forcibly stretched. The blood was removed from the joint by peroxide and a 1 per cent. solution of formalin. The wound was closed without drainage. The arm was put up in extension on a posterior splint. On October 1st, the tension sutures were removed. There was passive flexion and extension of 10° , but there was no power to extend the fingers. On October 5th, the splint

was removed and the patient encouraged to try elbow motions. During October the remaining sutures were removed and a small dressing applied. At this time pronation and supination were about 15° and flexion 90°. On October 22nd, the patient was referred to the Zander de la Chapelle Institute for massage and passive movements.

Final Results of Arteriovenous Anastomosis for Thrombo-Angiitis Obliterans.—Dr. WILLY MEYER presented these cases which were to illustrate some of the points brought out in his paper.

Conservative Surgery in Gangrene of the Toes.—Dr. RICHARD LEWISOHN presented two cases of gangrene of the toe, one diabetic, the other arteriosclerotic in origin.

CASE I.—This was a woman, forty-one years old, with a moderate diabetes. She had suffered from a badly infected toe for two weeks before her admission to Mount Sinai Hospital. The big toe and the first metatarsal bone were removed and the wound healed by primary union.

CASE II.—This patient was operated on in the same manner over one year ago at the Beth Israel Hospital. The pains which had been very severe disappeared right after the operation and the wound healed in about six weeks. In this instance the gangrene of the toe was caused by arteriosclerosis.

Dr. Lewisohn drew attention to the fact that utmost conservatism was indicated in these cases. Generally these patients were advised to undergo amputation of the thigh. His results showed that even in an amputation near the gangrenous and infected area they could obtain perfect results and thus save the leg of the unfortunate patient.

Remarks on the Conservative Treatment of Gangrene Due to Thrombo-Angiitis Obliterans.—Dr. WILLY MEYER reviewed some of the work he had done on this subject and again reported two cases of artificial hyperemia in threatened gangrene of the foot due to diabetic endarteritis which were reported in the *Annals of Surgery* (Vol. LII, page 713.). The first was a man, sixty years old, on whom he did an amputation of the thigh in 1907 for dry rapid spreading gangrene of the toes and foot. One and a half years later the patient began to show evidences of beginning gangrene of the opposite foot; several toes became affected and it was decided to try artificial hyperemia. A suitable hot air apparatus was used and faithfully carried out and the gangrenous process affecting the remaining foot was overcome, not one of the toes necrosing. The second case was a man, also sixty years old, with beginning gangrene of the toes of both feet, with some edema and threatening pain which indicated an extension of the process. A hot air apparatus was provided and the result of treatment was beyond their expectations. The threatened gangrene failed to extend and the bluish discoloration of the toes disappeared and the patient remained in good health. Dr. Meyer thought that as a matter of fact this treatment would be successful in a certain number of cases only and that it meant an addition to their therapeutic resources and deserved further trial. This was not employed in the moist form of gangrene. Dr. Meyer reported some patients he had injected with Ringer's solution and was very enthusiastic over the final results obtained. He also showed patients operated on by him showing the final results in arteriovenous anastomosis for thrombo-angiitis obliterans.

Dr. LEO BUEGER said that he could not be quite as enthusiastic as Dr. Willy Meyer, as to the final results of injecting Ringer's solution for thrombo-angiitis obliterans. He certainly felt with the other members of the Society that Dr. Meyer ought to be congratulated on his results, but he did not think that any permanent effect could be obtained by altering the viscosity of the blood in the cases of this disease. For histological examination and the study of many limbs had demonstrated very thoroughly to him that arteries and veins were already closed over considerable expanse of territory, that they were completely obstructed and organized, and that alteration of the viscosity of the blood could hardly make for improvement of circulation through such vessels; nor could one accept the theory that increase or diminution of the fluidity of the blood, and diminution of its viscosity could prevent the progressive nature of the disease since the increase of symptoms was not altogether due to the advent of new areas of thrombosis. Most of the cases treated by the conservative method did improve for a time. Many of them improved without treatment with mere

prophylaxis. Many of them returned after all sorts of treatment, diathermic, hot air, Ringer's solution, only to require amputation at a later date. Dr. Buerger did not wish to be understood as not being in favor of conservative treatment, but he wished to warn against the too hasty acceptance of the results of special lines of conservative treatment, as indicating the presence of specific therapeutic worth because of the vagaries of prognosis in this disease.

Dr. ABRAHAM LEON GARBAT said he wished to speak of two points that were of special interest: the character of the blood in these people and the amount of sodium citrate that could be infused. He called attention to the normal agglutination of human red blood cells by the serum of another human being, so-called iso-agglutination. In the early development of this study it was thought that the agglutination of the red blood corpuscles by the serum of another human being was pathological, but later on it was found to be a normal phenomenon. The remarkable fact was brought out that human beings could be divided into four distinct and sharply defined groups according to agglutinating properties of their blood. The serum of the first group agglutinated the red blood cells of all other groups. The red blood cells of Group 1 were not agglutinated by any human serum. In Group 2 the blood serum agglutinated the red blood cells of Groups 3 and 4; the red blood cells were only agglutinated by the serum of Groups 1 and 3. Group 3 was the reciprocal of Group 2. In Group 4 the serum did not agglutinate any red cells, but the red blood cells were agglutinated by all the others. These group characteristics were permanent and, furthermore, the agglutinating characteristics were hereditary. Group 1 comprised from 50 to 60 per cent. of all people. Of four cases of thrombo-angiitis obliterans, three belonged to the rare third group and one to the rare fourth group. It is possible that this finding was merely coincidence; at the same time further observations along these lines should be made. Another important point was in reference to sodium citrate. Its effect upon thrombo-angiitis obliterans was yet to be studied further. With regard to the method of sodium citrate transfusion, he believed that success depended upon two factors, whether the blood cells were viable when the transfusion was given, and whether the sodium citrate *per se* was harmless. As for the first, future experience only would tell. As for the second, sodium citrate had been found to be absolutely harmless, 19.5 grams having been given without any bad effect whatever.

Dr. DEWITT STETTEN said that he did not agree entirely with Dr. Meyer in what he stated regarding the arteriovenous anastomosis for thrombo-angiitis obliterans. This was a dangerous and unphysiological operation and should be in his opinion discarded. His conclusions were based upon injection experiments. He thought Dr. Meyer did not give him full credit for the interpretation of his experiments which were a comparative study of injections of both arteries and veins. The arteries acted so much better than did the veins that there was practically no comparison to be made at all. He did not believe there was any justification for arteriovenous anastomosis at all from an experimental basis. With regard to the results of this operation Dr. Stetten said he had collected 136 cases altogether and he found that there was a 30 per cent. mortality, 72 per cent. absolute failures, and 11 per cent. successes. With regard to the successes so-called, he believed they occurred in spite of and not as the result of the treatment. He also believed that the work of Horsley and Whitehead had confirmed his own experiments and supported his conclusions that this operation was not a justifiable one. He agreed with Guthrie, who had claimed that an experimental reversal of the circulation was possible, but who deplored the fact that the operation had been applied to the human being.

Dr. CHARLES GOODMAN said he differed with Dr. Stetten as to the value of arteriovenous anastomosis for thrombo-angiitis obliterans. Dr. Meyer's case was not the only one that improved after this operation. It should be remembered that the measures discussed so far showed a relief of the symptoms for a time only. He referred to two cases in which he had performed arteriovenous anastomosis in order to do a conservative amputation, that was, below the knee; in one week or ten days after the venous anastomosis there was hemorrhage from the veins and an arterial hemorrhage from the venæ comites.

Dr. WILLIAM C. LUSK said he was aware that in sug-

gesting syphilis as the possible cause of thromboangiitis, he was sounding an unpopular note, but that out of five cases of this disease which he had had under observation, in three the Wassermann had been positive. In one of these three cases the Wassermann had at first been negative for about a year and then following the giving of antisyphilitic treatment, had become positive. In another of these five cases, though the Wassermann has always been negative, the patient had a positive history of luetic infection with secondary manifestations, and the symptoms of his thromboangiitis became controlled following the use of the antisyphilitic remedies. In the fifth case there was no history of syphilis and the Wassermann was negative. Two of the five cases had regained their health and two had been benefited with the use of the antisyphilitic remedies in conjunction with the four-cell electric bath of Dr. Schnee (*Annals of Surgery*, LVIII, 1913, p. 670). One case (Wassermann positive) in the course of four months of the same treatment received no benefit. The electric baths caused this patient pain, but he had an open wound of the foot which was not protected from the action of the electrolysis, which latter was afterward learned to be irritating to the ulcerations of this disease. In administering the antisyphilitic remedies, mercury salicylate not more than one grain should be given by injection every five days for about three months, and potassium iodide in ten grain doses for four or five months prior to giving neosalvarsan. Dr. Lusk said he wished to emphasize the fact that the four-cell electric bath properly administered, *did* relieve or ameliorate the pain for varying lengths of time, sometimes at the beginning only for half an hour to an hour, but that with continued use, in conjunction with the antisyphilitic treatment, the intervals of respite grew longer so that the patients could get some continuous sleep. The current should be 10 ma. and the duration of the bath should be for ten minutes. Two of these baths a day could be given to relieve the pain. Any ulcerated area should be thickly covered with lanolin to protect it from the action of the electrolysis, since if not thus protected the electric bath would cause pain instead of relieving it.

Dr. WILLY MEYER said that he would be the last to minimize the work and investigations of Horsley and others. He did believe, however, that one successful clinical case was worth more than any reported experience upon a case after a limb had been amputated. He looked at the results or the conclusions at a different point of view. Personally he believed that without enthusiasm one could not make any progress; at the same time he withheld as much of his enthusiasm over these cases as was possible. He said he had tried for two years to see just what there was in the treatment; how to explain the results he left for the future to decide.

Bone Metaplasia.—Dr. FREDERICK W. BANCROFT presented this paper, in which he said that many theories had been propounded concerning the processes of repair of bone following trauma. The main point of contention was whether or not the periosteum was a definite osteogenetic membrane. Any explanation of the formation and repair of bone after trauma must be comprehensive enough to include the formation of bone in human arteries, the formation of bone in myositis ossificans and the experimental formation of bone in the kidneys, bladder, and aorta of animals. After reviewing some of the recent views on this subject the writer stated that in the study of bone repair, the origin of the bone cells was the all-important question. Was it a specific cell, and if so what was its origin? Did it spring from the periosteum alone? Did it, as MacEwen suggested, grow out from the Haversian canals? Could it spring from the surrounding connective tissue by a process of metaplasia? In order to answer some of these questions, if possible, the writer had attempted to study the process of the repair of bone by performing simple experiments, and examining microscopically the specimens at various lengths of time following operation. Bone cavities were made by denuding the humerus of periosteum for a distance of 4-6 cm., and making a rectangular cavity about 0.5 by 1 cm. in its shaft extending into the medullary canal. The canal was thoroughly curetted to remove the endosteum, and an attempt was made to establish complete hemostasis, in order to have an empty cavity in the bone. It was found that by plugging the medullary canal at both ends of the cavity with Moseley's bone wax, complete hemostasis could be produced, although on section later it was

found that the cavity had been filled with blood clot. At different lengths of time these animals were sacrificed and longitudinal sections of the bone made. Four of the animals experimented on in this manner jumped from elevations and fractured their legs at the site of the previous operation. These fractures were studied at different lengths of time afterward in order to observe the process of repair. During the past year experiments had also been made on the radius. A piece of the shaft about 2 by 4 cm. in length was excised, and the periosteum and endosteum curetted away; the periosteum was also removed for a distance of 2 cm. from the cut ends of the radius. The excised piece was cut into fragments 1 by 2 mm. in size, and these were replaced between the cut ends of the radius and the muscle sutured over them. Sections of these fragments had been most instructive. In all instances the nuclei of the bone cells, with the exception of those at the periphery of the fragments, lost their staining reaction in from ten to twenty days. The process of repair in bone cavities, fractures and bone transplants was similar. A blood clot formed around the traumatized area, became organized by true granulation tissue, with fibroblasts growing in the periphery, and then young blood vessels. As the granulation tissue became organized, calcium salts were deposited in the perivascular areas forming a very definite new bone. At a later period, the bone areas increased in size at the expense of the areolar tissue, the latter gradually changing from areolar to fibrous connective tissue. Sections under high power showed gradual gradations of the cellular elements; from connective tissue to bone; from connective tissue to fibrocartilage; and from fibrocartilage to bone. Normally this change could be seen at the entrance of a tendon. In the experimental work on a fracture, for instance, if the section was studied from the muscle tissues toward the site of the fracture, a gradual change in the character of the cells was observed. The fibrous tissue cells and fibroblasts became by gradations irregular in contour, the staining reactions changed, and little by little the cells took on the character of osteoblastic cells. Frequently areas of fibrocartilage were found in a zone between the fibrous tissue and the newly formed bone; in such instances the fibrous tissue gradually changed into cartilage, the cells took on capsules, and the collagen fibers shaded into the cartilage matrix. Then on the internal surface there was a metaplasia again between the cartilage and bone cells; the nuclei became irregular, the cell body lost its capsule, and the staining reaction changed from blue to pink, when stained by hematoxylin and eosin. All stages of gradation could be observed. In the repair of bone fragment transplants, the initial process was hemorrhage, with secondary formation of granulation tissue, as described. At a slightly later period, ten to twenty days after operation, the bone cells in the central portion of the fragments lost their staining reaction, while those at the periphery, where there is an adequate blood supply, were still visible. New bone was seen forming about all the fragments in the granulation tissue; at later periods the blood supply was reestablished through the Haversian canals of the transplants, and two or three concentric layers of bone cells with normal staining nuclei were found about the larger canals. There were areas of rarefaction and of new bone formation. In the embryo early formation of bone arose from the metaplasia of embryonal connective tissue, and later stages showed metaplasia from connective tissue to cartilage and from connective tissue to bone; cartilage cells were always broken down in front of the new bone formation. If it was assumed that, after trauma, new bone was formed in connective tissue, all the irregular formations of bone could be explained. In other words, if the proper stimulus was produced, and it was possible that this stimulus might be a positive chemotaxis exerted by the freshly exposed bone surfaces, lime salts might be so deposited upon connective tissue cells that metaplasia occurred and true bone was formed. In the kidney and bladder, where the urine contained a fairly high amount of calcium salts, it was easy to conceive that some interference with the blood supply might produce the change necessary. In this way myositis ossificans and new bone in arteries could be produced by metaplasia and likewise spurs along tendons. The periosteum was a definite connective tissue structure and therefore undoubtedly formed new bone when the proper stimulus was forthcoming, but it did not form bone when transplanted and the stimulus was absent, nor was it reasonable to suppose that it

was the only connective tissue structure from which new bone and cartilage could be formed.

Dr. BUEGER said that he agreed with Dr. Bancroft's very lucid and interesting exposition, believing, too, that metaplasia of connective tissue was the most important method of bone formation, in the case of bone transplants. Dr. Buerger himself in collaboration with Miss Oppenheimer had made a study of bone formation in sclerotic arteries in 1907 and 1908, and had pointed out at that time that, given the factors, lime, hemorrhage, with the organization of the extravasated blood by fibroblasts and angioblasts, they had all the necessary factors for the production of new bone. In the case of the arteries, they had found, that by virtue of some stimulus, be it an organizing thrombus, or an attempt at vascularization of the obliterating pathological intima, or possibly in the presence in the diseased mesial coat of lime alone, a penetration of the media with vessels took place. This was followed by the proliferation of young connective tissue in the media which came into contact with the lime; at such points of meeting the young connective tissue cells manifested a new function by producing the ground substance of true bone. The same factors, the presence of blood, attempt at organization, and lime, were present also in the case of bone transplants. Here, then, were all the necessary conditions for the conversion of the connective tissue into bone by a process of metaplasia.

Dr. FRED H. ALBEE said in reference to the osteogenetic potency of the detached periosteum that in 1911 he did a large amount of experimental work on the dog along these lines. He proved to his own satisfaction that this question depended wholly on what elements were included in the periosteal membrane which was separated from the bone cortex. Almost without exception anatomists and histologists described the periosteum as consisting of an outside fibrous layer, a vascular loose layer and an inside osteogenetic layer in the form of stratum of an embryonic type of bone cell. The natural area of cleavage in a normal bone was through the vascular layer which left the osteogenetic layer on the bone. This was demonstrated by his experiments which were published in the *Journal of the American Medical Association*, April 5, 1913. Whenever the dog's ulna was removed subperiosteally and a sharp elevator was used with an effort to secure a deep cleavage, active bone growth always occurred from the periosteum left in the limb. When the ulna was removed by a blunt instrument without an effort to get into a deep cleavage the periosteal membrane obtained (Macewen's limiting membrane) produced very little bone and this in the form of small plaques which apparently originated from adherent osteoblasts. The question whether the periosteum was osteogenetic or not resolved itself into whether the whole anatomical periosteum was obtained or not.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

LOUISIANA STATE BOARD OF MEDICAL EXAMINERS.

December 2, 3, 4, 1915.

ANATOMY.

1. What bones form the roof of the orbit?
2. Name the carpal bones that articulate with the radius.
3. Name and bound the triangles of the neck.
4. What muscles are inserted into (a) the outer ridge, (b) the inner ridge, of the bicipital groove?
5. Name the principal branches of the external carotid.
6. How is the jugular foramen formed? What important structures pass through it?
7. Name (a) the sensory, (b) the motor, nerves of the tongue.
8. Give origin and function of spinal accessory nerve.
9. Describe briefly the blood supply of the intestines.
10. What important structures are found between the layers of the broad ligament?

PHYSIOLOGY.

1. Describe the character of contractions observed (a) in striated muscles, (b) in non-striated muscles; give examples of each.
2. Give one example of a (a) nitrogenous food, (b)

carbonaceous food, (c) carbonitrogenous food; state what part each plays in nutrition.

3. Where, and how, are the nitrogenous foods digested?

4. Give the distribution and functions of (a) the hypoglossal nerve, (b) the spinal accessory nerve, (c) the superior laryngeal nerve.

5. What is the vasomotor system, and how does it influence the blood supply of the body?

6. Name the chief waste products of proteid metabolism, and state where they are formed.

7. State the functions of the (a) anterior nerve-roots of the spinal cord, (b) the posterior nerve-roots of the cord.

8. What factors are concerned in the heart sounds (a) in diastole, (b) in systole?

9. State briefly the influence on the body temperature of (a) muscular work, (b) mental work, (c) age, (d) sleep.

10. Give briefly the action of (a) trypsin, (b) lipase, (c) succus entericus.

CHEMISTRY.

1. What is understood by the conservation of energy, and give an example.

2. What are the special characteristics of alkaloids in general; name three alkaloids.

3. Give examples of (a) oxides, (b) hydroxides, (c) normal salts, (d) basic salts. These can be stated either in ordinary language or by formulae.

4. Describe the contact method in testing for albumin in the urine.

5. What is the chemical composition of human milk?

6. What is ptyalin and explain its action?

7. What is hemoglobin; state some of its chief properties?

8. Give the most reliable chemical test for detecting blood.

9. What are the general properties of proteins?

10. Name two biliary pigments and by what test can they be recognized?

MATERIA MEDICA.

1. Name three emetics and give dose of each.

2. Give source and average dose of atropine.

3. How much opium is there in the following preparations: Pulvis ipecacuanhæ et opii; tincture opii camphorata.

4. Give the composition of lotio hydrargyri nigra.

5. How is nitroglycerin prepared? What precautions should be taken in handling it, and in what doses would you give it?

6. What is eserine? Give the average dose.

7. Write a prescription for a diuretic mixture.

8. Give dose properties and uses of santalin.

9. What action has ergot on the circulation; on the muscles? What is the dose of the fluid extract?

10. What is emetine? What is its dose and what is its action?

PATHOLOGY.

1. Explain the difference between secretion and excretion, giving example of each.

2. Give the difference between exudate and transudate, with an example of each.

3. Pus is the result of what?

4. Define atrophy. Give the varieties of atrophy.

5. What is an embolus; how formed, and state some of the sequels of embolism.

6. Give the pathology in gonorrheal arthritis.

7. What is the difference between stock vaccine and autogenous vaccine?

8. Describe the *Amæba coli*, and give method most used in the examination for the *Amæba coli*.

9. Describe a Paget's cancer, and where most found?

10. Describe a Charcot's joint.

THEORY AND PRACTICE OF MEDICINE.

1. Name five reflexes, and describe the manner of eliciting them.

2. State the symptoms, diagnosis, and treatment of amebic dysentery.

3. (a) What is the import of hematuria? (b) What conditions may give rise to it?

4. State the diagnostic value of a blood count.

5. Treat a case of endocarditis complicating rheumatic fever.

6. Differentiate acute morphinism, acute alcoholism, and apoplexy.

7. Treat a case of pernicious malaria.

8. Outline briefly the dietetic management of a case of chronic nephritis.

9. State the diagnosis and treatment of impetigo contagiosa.

10. (a) Describe locomotor ataxia; (b) state briefly the symptoms and physical signs in the initial and ataxic stages.

ANSWERS.

ANATOMY.

1. *Bones forming the roof of the orbit:* Frontal and sphenoid.

2. *Carpal bones that articulate with the radius:* Scaphoid and semilunar.

3. The ANTERIOR TRIANGLE OF THE NECK is bounded: In front by a line from the chin to the sternum; behind by the anterior margin of the sternomastoid; base is upward, and is formed by the lower border of the body of the lower jaw and a line from the angle of the jaw to the mastoid process. It is divided into three smaller triangles (inferior carotid, superior carotid, and submaxillary) by the digastric muscle and the anterior belly of the omohyoid. The inferior carotid triangle is bounded, in front by the median line of the neck; behind, by the anterior margin of the sternomastoid; and above, by the anterior belly of the omohyoid. The superior carotid triangle is bounded, behind by the sternomastoid; below by the anterior belly of the omohyoid; and above by the posterior belly of the digastric. The submaxillary triangle is bounded, above by the lower border of the body of the mandible and a line drawn from its angle to the mastoid process; below, by the posterior belly of the digastric and the stylohyoid; and in front, by the anterior belly of the digastric.

The POSTERIOR TRIANGLE OF THE NECK is bounded: In front by the sternomastoid; behind, by the anterior margin of the trapezius; and its base corresponds to the middle third of the clavicle. It is divided into two smaller triangles (the occipital and the subclavian) by the posterior belly of the omohyoid. The occipital triangle is bounded in front, by the sternomastoid; behind, by the trapezius; and below, by the omohyoid. The subclavian triangle is bounded above, by the posterior belly of the omohyoid; below, by the clavicle; and in front, by the sternomastoid.

4. To the outer bicipital ridge is attached the Pectoralis major; to the inner bicipital ridge is attached the Teres major.

5. *Branches of the external carotid artery:* Superior thyroid, lingual, facial, occipital, posterior auricular, ascending pharyngeal, superficial temporal, and internal maxillary.

6. The jugular foramen is formed by the temporal bone in front and externally, and the occipital bone behind and internally; it transmits: The inferior petrosal sinus, lateral sinus, meningeal branches of occipital and ascending pharyngeal arteries, and the glossopharyngeal, vagus, and spinal accessory nerves.

7. TONGUE. *Sensory nerves:* Lingual branch of the inferior maxillary division of the trigeminal (ordinary sensation to anterior two-thirds), chorda tympani (nerve of taste for anterior two-thirds), glosso-pharyngeal (general sensation and taste to posterior third). *Motor nerve:* Hypoglossal.

8. SPINAL ACCESSORY NERVE. *Superficial origin:* From the lateral tract, inferior to the pneumogastric; and from the side of the spinal cord as far down as the sixth cervical nerve. *Deep origin:* From the anterior horn of gray matter of the medulla, and of the spinal cord as far down as the fifth cervical nerve. *Function:* Motor nerve to the sternomastoid and trapezius muscles.

9. BLOOD SUPPLY OF THE INTESTINES. *Duodenum:* Pyloric and pancreaticoduodenal (of the hepatic), and inferior pancreaticoduodenal (of superior mesenteric). *Jejunum and ileum:* Branches of the superior mesenteric artery. *Cecum and appendix:* Ileocolic and appendicular arteries. *Colon:* Right colic and middle colic (of superior mesenteric), left colic and sigmoid branches (of inferior mesenteric). *Rectum:* Superior hemorrhoidal (of inferior mesenteric), middle hemorrhoidal (from internal iliac), and inferior hemorrhoidal (from internal pudic artery).

10. *Structures between the layers of the broad ligament:* Fallopian tube, round ligament, ovary, ovarian ligament, parovarium, loose connective tissue, vessels and nerves.

PHYSIOLOGY.

1. *During contraction*, the following changes take place in a voluntary (striated) muscle: (1) It becomes shorter and thicker, but (2) there is no change in volume; (3) there is an increased consumption of oxygen; (4) more carbon dioxide is set free; (5) sarcolactic acid is produced; and hence (6) the muscle becomes acid in reaction; (7) it becomes more extensible, and (8) less elastic; (9) there is an increase in heat production and consequently a rise of temperature; (10) the electrical reaction becomes relatively negative, and (11) a sound is produced. Further, a single stimulus produces a simple contraction; a series of rapid stimuli produces a condition of tetanus, but of an incomplete kind. Involuntary (non-striated) muscle acts differently: The duration of the contraction is prolonged; there is a tendency to rhythmical contraction; peristalsis is also a characteristic of this class of muscle; involuntary muscle cannot be thrown into tetanus. *Voluntary muscle* is found in all the skeletal muscles, pharynx, diaphragm, larynx, external ear, and eye. *Involuntary muscle* is found in the alimentary tract from the middle third of the esophagus to the anus, in the ducts of glands, in the trachea and bronchial tubes, within the eyeball, the internal urinary and genital systems, circulatory (except the heart) and lymphatic systems, and the capsules of some organs.

2. A nitrogenous food, peas; a carbonaceous food, sugar; a carbonitrogenous food, sweetbread.

FOOD.

Proteids.

1. All substances containing nitrogen, of a composition identical with, or nearly that of albumin; proportion of N to C being nearly as 2 to 7.
2. Substances containing a larger proportion of N are apparently less nutritious; proportion of N to C about 2 to 5½.
3. Extractive matters, such as are contained in the juice of the flesh.

Carbohydrates.

Substances containing no N, but made up of C, H and O; the O being exactly sufficient to convert all the H into H₂O.

FUNCTIONS.

Formation and repair of tissues and fluids of the body.

Regulation of the absorption and utilization of oxygen.

May also form fat and carbohydrate, and yield energy sometimes.

These perform the above functions less perfectly, or only under particular circumstances.

These substances appear essentially as regulators of digestion and assimilation, especially with reference to the gelatin group.

Production of energy and animal heat by oxidation. Form fats and possibly some proteids.

3. Nitrogenous foods are digested: (1) In the stomach where the pepsin, in the presence of dilute hydrochloric acid, causes hydrolysis of the protein molecule, splitting it up into smaller and more soluble molecules. The stages of gastric digestion are from protein to globulin, to metaprotein, proteoses and peptones. (2) In the intestine, where the trypsin of the pancreatic juice, in a slightly alkaline medium, performs a somewhat similar function as the pepsin of the gastric juice; only, here, the process is continued further, and the proteoses and peptones are further broken up into polypeptides and amino-acids.

4. The HYPOGLOSSAL NERVE is distributed to the muscles of the tongue, to the thyrohyoid, and to the omohyoid, sternohyoid and sternothyroid muscles. *Function:* Motor to the tongue. SPINAL ACCESSORY NERVE. *Distribution:* After emerging from the cranial cavity the nerve soon separates into two branches: (1) An internal or anastomotic branch, consisting chiefly of filaments coming from the medulla oblongata. It soon enters the trunk of the vagus, from which fibers pass to the muscles of the pharynx, to the muscles of the larynx through the inferior laryngeal nerve, and to the heart according to most authorities. (2) An external branch, consisting chiefly of the accessory fibers from the spinal cord. It is distributed to the sternocleidomastoid and trapezius muscles.

Function: The transmission of nerve impulses from

the cells from which they take their origin to the muscles to which they are distributed. They therefore excite to action some of the muscles of deglutition, the muscles which regulate the tension of the vocal bands during phonation, and the muscles which control the respiratory movements associated with sustained or prolonged muscle efforts; the fibers also convey nerve impulses which exert an inhibitory influence on the heart; it is the motor nerve to the trapezius and sternomastoid. (From Brubaker's *Physiology*.)

SUPERIOR LARYNGEAL NERVE. *Distribution:* Larynx, cricothyroid muscle. *Function:* Sensory to the larynx, and motor to the cricothyroid muscle.

5. The vasomotor nervous system consists of (1) a vasomotor center in the bulb, (2) of some subsidiary centers in the spinal cord, and (3) of vasomotor nerves, which are of two kinds: (a) those causing constriction of the vessels, and so-called vasoconstrictor nerves; and (b) those causing dilatation of the vessels, and so-called vasodilator nerves. These nerves supply the muscle tissue in the walls of the blood-vessels and regulate their caliber, thus influencing the *quantity* of blood supplied to a part; at the same time they regulate the *quality* of blood supplied to a part; they also regulate the *nutrition* of a part, also *secretion* and *heat production*. They are concerned, too, in the control of the heart-beat. The center is in the medulla, in the floor of the fourth ventricle, near the calamus scriptorius.

6. *The chief waste products of proteid metabolism are:* Urea, ammonia, creatin, creatinin, hippuric acid, sulphates, various purin bases (chiefly uric acid).

Most of the *urea* is formed in the liver, from (1) the amino acids which have been absorbed from the small intestine, and which are not needed by the body; and (2) from the ammonium carbonate which is derived from the tissues, and from the action of a uricolytic enzyme upon uric acid. These two sources give respectively what is known as *exogenous urea* and *endogenous urea*.

Uric acid: "In man uric acid has a twofold origin; one portion, coming from the breaking down of the nuclein-containing tissues or cell elements of the man's own body, and hence is of endogenous origin, while the other portion—usually the larger—is of exogenous origin, coming from the transformation of free and combined purin compounds present in the food."—(Chittenden.)

Hippuric acid has its origin in the kidney; and creatin and creatinin in muscle and other tissues.

7. The anterior nerve roots of the spinal cord are *motor*; the posterior nerve roots are *sensory*.

8. The *causes* producing the *first* sound of the heart are not definitely ascertained. The following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

The first sound is synchronous with the ventricular systole; and the second sound with the first part of the ventricular diastole.

9. *Muscular work* increases the body temperature; *mental work* slightly increases the body temperature; *age* exerts a slight influence, as the temperature of the child is generally a little higher than that of the adult; and the temperature of an old person is a little lower than that of the adult; *sleep* diminishes the body temperature by lessening the production of heat.

10. *Trypsin* converts proteins into proteoses, peptones, polypeptides, and amino-acids, in an alkaline medium. *Lipase* splits fats into glycerol and fatty acids.

Succus entericus converts starch into dextrin and then into dextrose and levulose; it also splits polypeptides into amino-acids and ammonium compounds; it converts sugars into dextrose, levulose, and galactose.

CHEMISTRY.

1. *Conservation of energy.* When one form of energy disappears, an exact equivalent of another form of energy takes its place. Thus heat may be converted into motion, and motion into chemical energy; but in each case there is exactly the same amount of energy present.

2. *Alkaloids* are nitrogenous, basic substances, of alkaline reaction, and capable of uniting with acids to form salts in the same way that ammonia does. Most alkaloids are solid, crystalline, contain carbon, hydrogen, nitrogen, and oxygen, are sparingly soluble in water,

but are soluble in alcohol, their salts are freely soluble in water, they are generally bitter in taste. *Three alkaloids:* Morphine, atropine, quinine.

3. *Oxides:* Sulphur dioxide, SO_2 ; ethyl oxide ($\text{C}_2\text{H}_5\text{O}$).

Hydroxides: Potassium hydroxide, KOH ; ethyl hydroxide, $\text{C}_2\text{H}_5\text{OH}$.

Normal salts: Dipotassic sulphate, K_2SO_4 ; calcium carbonate, CaCO_3 .

Basic salts: Lead carbonate (of the pharmacopœia), $(\text{PbCO}_3)_2$, PbH_2O_2 ; so-called, bismuth subnitrate, BiONO_2 .

4. *The contact method in testing for albumin in the urine:* Put a small amount of nitric acid into a test-tube; fill a pipette with the filtered urine; hold the test-tube at a small angle to the horizontal and allow the urine to flow slowly from the pipette upon the surface of the nitric acid. Remove the pipette, and gently turn the test-tube into the vertical position; a milky zone at the junction of the nitric acid and urine denotes the presence of albumin.

5. *Human milk* is composed of almost 87 per cent. of water and 13 per cent. of solids. The latter are: Fat, about 3.5 per cent.; milk sugar, about 6 per cent.; protein about 4 per cent.

6. *Ptyalin* is an enzyme found in the saliva. Its action is to turn starches into maltose. It acts only in an alkaline medium, and acts best at about the body temperature; it is necessary to remove the products of its activity.

7. *Hemoglobin* is a proteid coloring matter containing iron, and is present in the red blood corpuscles. It is of very complex constitution; it readily absorbs oxygen from the air, and forms oxyhemoglobin; it is the oxygen-carrying part of the blood, conveying the oxygen from the lungs to the various tissues of the body; it gives a characteristic spectrum band.

8. *The best chemical test for blood,* is the formation of hemin crystals. These crystals are obtained by boiling a fragment of dried blood with a drop of glacial acetic acid on a slide; the characteristic crystals may be seen with the microscope.

9. Proteins are very complex organic compounds, consisting of carbon, hydrogen, oxygen, nitrogen, sulphur, and other elements. They are split up by pepsin and trypsin into proteoses, peptones, polypeptides and amino acids; they are insoluble in alcohol and ether, most of them are insoluble in water, but some are capable of entering into a state of colloidal solution; they are soluble in the gastric and pancreatic juices. Most of them are coagulated by heat; they are colloids, are levorotatory, and give many color reactions.

10. *Two biliary pigments:* Bilirubin and biliverdin. *Gmelin's test for bile pigments* consists of a play of colors—green, blue, red, and yellow—produced by the action of fuming nitric acid.

MATERIA MEDICA.

1. *Three emetics:* Apomorphine hydrochloride, dose 1/10 grain used hypodermatically. Copper sulphate, dose gr. iv. Zinc sulphate, dose gr. xv.

2. *Atropine* is an alkaloid of *Atropa Belladonna*; the average dose is 1/160 grain.

3. *Pulvis ipecacuanhæ et opii* contains 10 per cent. of opium; *Tinctura opii camphorata* contains about one grain of opium to the half ounce.

4. *Lotio hydrargyri nigra* contains thirty grains of calomel to ten ounces of lime water.

5. *Nitroglycerin* is prepared by the action of a mixture of nitric and sulphuric acids upon glycerin. The spirit of nitroglycerin is given in doses of one minim. It should be kept in well-stoppered tin cans, in a cool place, away from lights and fires, and should be very carefully handled because, if a considerable quantity of it is spilled a violent explosion may occur.

6. *Eserine* is an alkaloid of physostigma. The dose of the salicylate and sulphate is 1/64 grain.

7. *Prescription for a diuretic mixture:*

R.
Potassii acetatis.
Potassii bitartratis.
Potassii citratis aa 3ij.
Aq. q.s. ad ʒviii M.

Sig.:—Take one tablespoonful, well diluted, three times a day.

8. *Santonin* is obtained from *Santonica*, which is derived from *Artemisia pauciflora*; it is used as an anthelmintic to round worm and thread worm; dose, for a child, gr. ¼-½; for an adult, gr. j or ij.

9. *Ergot* stimulates and causes contraction of in-

voluntary muscle fibers, hence it is vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative; it raises the blood pressure, it increases peristalsis, and is an emmenagogue. The dose of the fluid extract is thirty minims.

10. *Emetine* is an alkaloid of *Cephaelis Ipecacuanha*; it is used as an expectorant and an emetic; the dose (as an expectorant) is 1/100 grain; (as an emetic), 1/6 grain.

PATHOLOGY.

1. A *secretion* is a liquid or semi-liquid product formed by glandular organs; as saliva.

An *excretion* is a product which is eliminated from a gland (or other structure); as urine.

Formerly, it was held that a secretion had some further use in the body; and that an excretion had no use, but that its further retention was dangerous. Another view, once held, was that in the case of an excretion the gland merely extracted the substance ready-made from the blood; whereas, in the case of a secretion, the gland was supposed to produce some of the constituents.

2. *Transudates* are pathological fluids of non-inflammatory origin, as in ascites. *Exudates* are pathological fluids of inflammatory origin, as in peritonitis.

Further, *transudates* do not coagulate spontaneously, contain but few cells, have specific gravity below 1018, and contain but few bacteria; *exudates* tend to coagulate on standing, have more cells and albumin, specific gravity is above 1018, and bacteria are generally present and are often numerous.

3. Pus is the result of inflammation plus the presence of pyogenic bacteria.

4. *Atrophy* is a decrease in the amount of a tissue owing to diminution either in the number (*numerical atrophy*), or in the size (*simple atrophy*) of the histological elements of which the tissue is composed.

5. An *embolus* is a plug in the circulation; the process is called embolism. *Causes*: Thrombi, detached pieces from the heart valves, microorganisms, oil, fat, parasites, pieces of new growths. *Results*: Obstruction to the circulation; infarction; inflammation of blood-vessel; dilatation of blood-vessel.

6. "*Gonorrheal arthritis* is due to the gonococcus, which is carried by way of the blood from the urethra, or rarely from the conjunctiva in gonorrheal ophthalmia. As a rule, it appears during the subsiding stage of an acute gonorrhea or in chronic cases. One or several joints may be involved, generally the former, the knee, ankle, and wrist being most frequently affected. The inflammation may be acute or chronic, and varies in extent as well as in degree. Although the synovial membrane alone may be involved, the ligaments and periarticular structures are very apt to be thickened and infiltrated. Suppuration may occur, and ankylosis is very prone to follow even in the milder cases. Endocarditis and like complications of general infection occasionally occur." (Stewart's *Surgery*.)

7. *Stock vaccines* are made from the same kind of bacteria as those causing a given infection, but are not derived from the patient; *autogenous vaccines* are made from bacteria freshly isolated from the patient himself.

8. The *Amœba coli* is a colorless, granular cell, about 10 to 20 μ in diameter, with a nucleus which is distinct, and pseudopods; it is found in the stools. To examine for the *Amœba coli*, the stool should be passed in a warm vessel, and kept warm till the examination is complete; a warm stage should be used.

9. *Paget's disease* is an eczematous inflammation of the nipple and areola, with a tendency to ulceration; it is, in very many cases, the starting point of a carcinoma. It has been asserted that the condition is due to the presence of coccidia, but this has not been proved. The nipple may be retracted, there is a moist desquamation, followed by a sticky discharge and formation of crusts; under the latter, the surface is raw and red. In some cases the nipple may be completely destroyed.

10. "*Charcot's joint* is a joint affection observed in posterior sclerosis, syringomyelia, poliomyelitis, transverse myelitis and a few other forms of spinal disease. The joints usually affected are the knee, hip, shoulder, elbow, hand, foot, and more rarely the fingers. The disease is rather rapid and is quite destructive, thickenings and ulcerations forming upon the synovial membrane and ligaments. Serous exudates and inflammations of the peri-articular tissues occur, and spontaneous luxation is not infrequent. The cause of the affection is supposed to be atrophic neurosis. In gen-

eral, the pathologic changes resemble those of arthritis deformans." (McFarland's *Pathology*.)

THEORY AND PRACTICE OF MEDICINE.

1. **FIVE REFLEXES.** *Plantar*: elicited by stroking or scratching the sole of the foot, when the patient attempts to withdraw the foot. *Tendo Achillis reflex*: when the leg is extended and supported at the knee, and the hand is pressed firmly against the ball of the foot, a tap on the tendo Achillis causes contraction of the gastrocnemius and soleus, and the heel is jerked up. *Patellar reflex*: when the thigh is supported by being crossed over the other thigh, and the leg is flexed at the knee, a tap on the quadriceps tendon just below the patella causes the leg to be suddenly extended. *Ankle clonus*: if the half-extended leg be supported at the knee, and the ball of the foot be suddenly pressed up, putting the tendo Achillis on the stretch, there sometimes results a series of contractions of the muscles of the calf with alternate extension and flexion of the foot, which continues so long as pressure is maintained on the ball of the foot and ceases when the pressure is released. *Cremasteric*: when the inner surface of the thigh is irritated, the testicle on the same side is retracted.

2. **AMEBIC DYSENTERY.** *Symptoms*: It is usually ushered in by an attack of diarrhea, accompanied by slight fever, nausea, and vomiting. There are intense abdominal pain and a constant desire to go to stool. The stools become more frequent and bloody. Tenesmus is worse in the afternoon and at night. Temperature may be normal or slightly elevated (100° F.). Intermittent missions occur in the disease, and the *Amœba coli* is found in the stools. The *diagnosis* is made by finding the microorganisms in the stools, in conjunction with the symptoms.

The *treatment* consists of rest in bed and liquid diet. Laudanum (30 drops), followed in half hour by ipecac, gr. 30, repeated, if necessary, has been recommended for internal administration. Rectal irrigations of plain water, silver nitrate solution (gr. 20-30 to the quart) creolin (4 drams to the quart), or quinine (1:5000 to 1:1000) constitute the best treatment. Pain is relieved by opium. Emetine hydrochloride, given subcutaneously or intravenously, is also recommended.

3. *Hematuria* means the presence of blood in the urine; when blood-pigment only (not corpuscles) is found in the urine the condition is called *hemoglobinuria*.

The *principal causes of hematuria* are: (1) Conditions in which the blood is affected, as in the infectious diseases, in scurvy, pernicious anemia, and purpura; (2) traumatism or inflammations in any part of the urinary tract; (3) congestion of the kidneys secondary to disease of the lungs, heart, or liver.

4. A *blood count* will settle the diagnosis of a pernicious and secondary anemia, leukemia (lymphatic and splenomedullary). Further, a leucocytosis is generally present in lobar pneumonia, pericarditis, empyema, acute rheumatism, erysipelas, cerebrospinal meningitis, typhus, relapsing fever, Asiatic cholera, bubonic plague, yellow fever, tonsillitis, appendicitis, septicemia, pyemia, and other inflammatory conditions. A leucopenia is found in typhoid, malaria, influenza, measles, pernicious anemia.

5. In *endocarditis complicating rheumatic fever*, the patient needs absolute rest in bed for a long period of time; care must be taken in the use of salicylates, as these tend to depress the heart; digitalis is indicated if the heart is failing, but care must be taken not to overstimulate the heart; light diet, milk, attention to the bowels, and sleep are of prime importance.

6. The following table is from Eisendrath's *Surgical Diagnosis*:

APOPLECTIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; sudden onset. If any injury, only a scalp wound.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.

APOPLECTIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse more rapid than normal, and full.	Pulse rapid, may be irregular.
Respiration slow and irregular.	Regular respiration.	Respiration very slow—may be 6 to 8 per minute.
Temperature higher on paralyzed side, but lower in rectum.	May be low or normal.	
Urine contains trace of albumin, but may be same as in uremia.	Normal.	Normal.
Hemiplegia with convulsions on one side.		

7. *Treatment of pernicious malaria:* The patient should be promptly cinchonized by the hypodermic injection of bisulphide or bihydrochloride of quinine (about 30 grains); or the muriate of quinine and urea in 15 or 20 grain doses may be similarly employed; intramuscular injection is said to be less painful than subcutaneous injection; methylene blue, in doses of 3 grains, in capsules or pills, has been recommended; Warburg's tincture, either with or without aloes, may be used; in the cold stage, heat may be applied to the body surface, and in the hot stage cold may be applied, and morphine administered hypodermically.

8. *In chronic parenchymatous nephritis, the diet is important.* "An exclusive milk diet is impracticable, even harmful. The cereals, with fruits and the lighter vegetables are all permissible. Meats in small quantity are allowable, either light or dark. The water intake must not be regulated by any hard-and-fast rule, but it should be proportioned to the freedom of diuresis. If there is marked edema, especially if it be on the increase, attempted flushing of the kidney is provocative of harm. Under these circumstances water is among the most difficult substances for the kidney to excrete. If the edema is slight or subsiding rapidly larger quantities of fluid are not only permissible but advisable. The intake of salt should be limited to the minimum, as it is pretty generally conceded that its presence in the diet aids the development of edema." (Williamson's *Practice of Medicine*.)

9. *In impetigo contagiosa, the eruption appears with the greatest frequency on the face and hands and often follows some very trivial injury, as a scratch.* As the lesions appear, their contents are clear, but within a day or so the vesicle or bleb character is lost and they assume all the features of pustules. The pustules rapidly dry, forming crusts which have a "stuck on" appearance. After several days these drop off, leaving a slightly red area beneath. Usually there are present at the same time several lesions in various stages of development. The vesicopustules may coalesce, forming several large blebs, or they may arrange themselves in half-circles. Itching is very slight or absent. Neglect or improper treatment may cause the development of an eczema or an impetiginous area. The duration of the disease is in most instances from ten days to two weeks. *Treatment:* The crusts should be removed by means of some nonirritating soap and water, after which an ointment containing ammoniated mercury and the red oxide of mercury may be applied. Other mild antiseptics, such as boric acid, sulphur, etc., may be employed, care being taken to reduce the strength sufficiently to avoid irritation." (Hughes' *Practice of Medicine*.)

10. *Locomotor ataxia* is a disease of the spinal cord, characterized by loss of coordination, characteristic and unsteady gait, a tendency to stagger when standing up with the feet together and the eyes closed, sharp and paroxysmal pains called *crises*, girdle sensation, Argyll-Robertson pupils, and loss of knee-jerk and other reflexes. In locomotor ataxia the posterior columns of the spinal cord and the posterior nerve roots are involved. The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion. The spinal ganglia

may also be affected and the membranes over the affected parts are adherent and opaque.

In the *pre-ataxic stage*, there may be found: Lightning pains, girdle pains, paresthesia, loss of knee-jerk, Argyll-Robertson pupil, ptosis, and optic atrophy. In the *ataxic stage*, there will be found: Incoordination, the ataxic gait, flaccidity of the muscles, loss of muscle sense, various visceral crises, perforating ulcer of foot, brittleness of bones, and Charcot's disease.

(To be continued.)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION
Alabama	W. H. Sanders, Montgomery	Montgomery, July 11
Arizona	J. W. Thomas, Phoenix	Phoenix, April 4
Arkansas	T. J. Stout, Brinkley	Little Rock, May 9
California	C. B. Pinkham, Sacramento	Los Angeles, April 4
Colorado	David A. Strickler, Empire	Denver, April 4
Connecticut	Chas. A. Tuttle, New Haven	New Haven, Mar. 14
Delaware	J. H. Wilson, Dover	Dover, June 20
Dist. of Col.	E. P. Copeland, Washington	Washington, April 11
Florida	E. W. Warren, Palatka	Jacksonville, June 13
Georgia	C. T. Nolan, Marietta	Atlanta, June 1
Iaho*	Charles A. Dettman, Burke	Boise, April 4
Illinois	C. S. Drake, Springfield	Chicago, May 4
Indiana	W. T. Gott, Crawfordsville	Indianapolis, July 11
Iowa	G. H. Sumner, Des Moines	Iowa City, June 1
Kansas	H. A. Dykes, Lebanon	Topeka, June 13
Kentucky	J. N. McCormack, Bowling Green	Louisville, June 1
Louisiana	E. L. Leekert, New Orleans	New Orleans, June 8
Maine	F. W. Seale, Portland	Portland, Mar. 14
Maryland	J. McP. Scott, Hagerstown	Baltimore, June 20
Massachusetts	W. P. Bowers, State House, Boston	Boston, Mar. 14
Michigan	B. D. Harrison, 205 Whitney Building, Detroit	Ann Arbor, June 13
Minnesota	T. McDavitt, St. Paul	Minneapolis, April 4
Mississippi	E. H. Galloway, Jackson	Jackson, June 13
Missouri	J. A. B. Adcock, Jefferson City	St. Louis, Mar. 20
Montana	Wm. C. Riddell, Helena	Helena, April 4
Nebraska	H. B. Cummins, Seward	Lincoln, June 1
Nevada	S. L. Lee, Carson City	Carson City, May 1
N. Hampshire	Walter T. Crosby, Manchester	Concord, June 26
New Jersey	A. MacAlister, Trenton	Trenton, June 20
New Mexico	W. E. Kaser, East Las Vegas	Santa Fe, June 1
New York	H. H. Horner, Univ. of State of New York, Albany	Albany, May 16
N. Carolina	H. A. Raster, Raleigh	Raleigh, June 1
N. Dakota	G. M. Williamson, Grand Forks	Grand Forks, July 4
Ohio	Geo. H. Matson, Columbus	Columbus, April 11
Oklahoma	R. V. Smith, Tulsa	Oklahoma City, April 11
Oregon	B. E. Miller, Portland	Portland, June 1
Pennsylvania	N. C. Schaefer, Harrisburgh	Philadelphia, April 11
Rhode Island	G. T. Swarts, Providence	Providence, June 13
S. Carolina	H. E. Booser, Columbia	Columbia, April 6
S. Dakota	P. B. Jenkins, Waubay	Pierre, June 13
Tennessee	A. B. DeLoach, Memphis	Memphis, June 1
Texas	M. P. McElhannon, Belton	San Antonio, June 20
Utah	G. F. Harding, Salt Lake City	Salt Lake City, April 3

THE USE OF TRICKERY TO DISCOUNT MEDICAL TESTIMONY.

BY EUGENE R. CORSON, B.S., M.D.,
SAVANNAH, GEORGIA.

THE following case presents certain interesting points in connection with medical expert testimony, and questions of bias and medical ethics, so that I do not hesitate to publish it, and in some detail.

A white man, *æt.* 31 years, a car inspector, on May 27, 1914, was inspecting the air brakes on a long train, when, without any warning, the train suddenly started, striking him on his right shoulder, and knocking him sideways and backward. To save himself from being crushed he caught on to some support by his left arm, and managed to throw his left leg over the axle of the car, with his right leg dragging. In this position he was dragged seven or eight car lengths, fearing every second that the dragged foot would be caught in a switch which he knew was not far off, and that he might be crushed into a bloody pulp. When the train was stopped, and he was taken from his perilous position, he was badly bruised and in a state of nervous collapse. For four days he suffered great pain in his back, shoulder, and hip, and was kept under opiates all that time. He was confined to bed eighteen days. At the end of six weeks his physician turned him over to an osteopath for massage, hoping thus to overcome the contracted muscles of the back and legs, and to relieve his pains.

Having entered suit against the road, his attorneys sent him to me for examination on July 29, two months after the accident, when I examined him in my office.

To me he gave a characteristic picture of a traumatic neurosis. Of his physical injuries there was no trace, but of the psychical or mental picture there was no doubt in my mind. He had been a car inspector for eight years, and had given satisfaction to his employers. He denied syphilis and gonorrhea, but admitted some drinking. There was a tonic contraction of the back and thigh muscles, causing him to walk bent over, and with a cane, as though in a plaster cast. There was a partial and irregular hemianesthesia of the left side, a hyperesthesia over the lower dorsal spine, and excessive knee-jerk. The only other noticeable reflex was the pupillary, which was pronounced on pressure over the lower dorsal spine, the pupil dilating when he flinched, to me an uncommon symptom. With this there was an increase in the pulse beat to one hundred or a little over. His blood pressure taken just before the trial was 130 mm. systolic, 82 mm. diastolic. He complained of constant pain in his back and legs, of frequent and difficult urination, of loss of sexual desire, and of poor sleep. There was

great emotional depression at the first examination. He wept while telling his story. There was evidence of lack of mental attention and concentration, and of aboulia—his facial expression bearing out his emotional and mental states. He weighed in my office 125 pounds, a loss of twenty pounds from his usual weight.

The wholly psychical character of the case led me to advise his lawyers to wait a sufficient time to try out his powers of recovery before going to trial. Altogether I went over him four times, the last time in my office the day before the trial, with the five physicians representing the road. During this interval of five months he gained ten pounds, had a better color and a fuller face, but I saw no change in his other symptoms.

I asked a specialist in whom I have every confidence, and who, by the way, happened to be the specialist for this very road, to examine his eyes and ears. He reported to me that he found no retraction of the visual field, which I thought might exist, but did find a 50 per cent reduction in the bone-conduction for the left ear, the same side on which I found the hemianesthesia on the back, which seemed to me to confirm the hysterical element in the case. The trouble was not in the middle-ear but in the internal ear.

And now to go back a little in my story and introduce a new character in this medicolegal drama. Early in October, I think, I have no record of the date in my card catalogue, a large, alert, and intelligent looking man came into my office, helped from a carriage by the driver, walking with difficulty and seemingly in much pain, and after settling himself in my most comfortable chair, gave me in substance the following history: He was from Jacksonville, and on his way to Virginia to settle an accident claim. After finishing his business he was to return to Savannah and enter the Savannah Hospital and place himself directly under my care. He said he was an engineer on the A. C. L. R. R. and that on July 2, 1914, while climbing up on a freight car the grab-iron gave way, and he fell a distance of 12 feet, striking on his buttocks and jarring his back and head. He was unconscious an hour, was laid up in bed five weeks; that he could get no satisfaction from the road, and that this, with certain inimical conditions in Jacksonville, induced him to come to Savannah and enter his suit here. He asked me if a certain firm of lawyers were good men (the same firm which was to try the present case), and asked me to give him a letter to this firm after my examination of him.

He walked with a high-stepping gait and his legs far apart. There was apparently excessive knee-jerk and great sensitiveness over the lower dorsal spine. He complained of great pain on any jar or movement. I find on my card record: "Vegetative life normal, urine normal, frequent urina-

tion; sexual function limited." He asked for a prescription to give him some temporary relief, at least, and I wrote him one for potassium bromide and aromatic spirits of ammonia. I gave him a letter to the lawyers mentioned, stating he was injured, and also made a similar statement to an accident company in Virginia.

A day or so later, the junior member of the law firm referred to told me he had seen this man, who had told him he had lost the letter I gave him, and he intimated to me that the man might not be honest. It is interesting to note how much more critical the mind becomes when any suspicion enters in. In rehearsing the case in my own mind I became aware of certain features not noted at the time, which I had taken in subconsciously and which only now came to the surface. The man was dramatic in his actions; he was in a hurry, and seemed oversensitive and anxious while I was eliciting his knee-jerk. The testimony at the trial showed he had very carefully prepared his part, and had with much skill worked out all its details and possibilities. His promise to me to return immediately to Savannah and place himself under my care in the hospital was a cunning ruse to throw me off my guard and to minimize my examination at the time. However, I gave the case no further thought, when, about six weeks before the case I have detailed came to trial, I got a letter from Jacksonville, purporting to come from this man's brother-in-law, in which he asked for information about the hospital expenses, and also making excuses for his brother's delay in entering the hospital as he had promised to do, and that he had been busy with his other claims. He stated further that he had the grab-iron which had caused his fall. His letter still further threw me off my guard. I kept no copy of this letter nor of the one I wrote in reply. As the man did not turn up at the hospital, we inclined to the belief that the case was not genuine. As I look back now I am surprised that I gave the whole affair so little after-thought or concern. I did tell the lawyer, however, that I felt the case might be sprung on me at the coming trial, but that I could easily defend myself. I simply would have to admit that I had been deceived by one paid to deceive, and skillful at the business; that I had seen the man but once, and for a short time which he had skillfully arranged, and that when I gave him this letter to the lawyers the case would have to be verified in all its medicolegal aspects before any decisive steps could be taken; and that my mistake could in no way lead to any injury to any party; it could lead to nothing but a cul-de-sac.

At the trial, soon after the cross-examination began, I saw the trap laid for me ready to be sprung, so that I was not wholly unprepared for the blow. Opposing counsel handed me the letter I had written and asked me if it was mine. I admitted the letter and the deception by a hired impostor; I admitted I had been over-credulous and over-hasty in my diagnosis on the spur of the moment; that in the practice of my profession I had been deceived many times before, and had made many mistakes, and would probably be deceived again and make more mistakes.

The physician who attended the plaintiff immediately after the accident, and for two months following, testified to the man's sufferings and to the genuineness of his symptoms. The osteopath who, of all who attended him and examined him, had had the best chance of knowing the tonically con-

tracted muscles and concomitant pains, through five months, testified the man's symptoms to be genuine.

The five doctors for the Railroad Company all testified that the man was normal and therefore a fake; though each one of them on the cross-examination admitted one or more abnormal symptoms. One admitted that the pulse was one hundred; one admitted that he had noticed the pupillary reflex; one admitted that he had noticed a difference in the sensitiveness of the skin on the two sides, and they all admitted when questioned concerning the impostor that one could be deceived on the first examination.

I testified on the stand that the plaintiff was suffering from a traumatic neurosis combined with some traumatic hysteria; that the condition was probably one of psychical shock, the result of the peculiarly distressing circumstances of the initial injury; that I considered the case genuine; that from our present knowledge of the subject these traumatic neuroses, including hysteria, were largely dependent on the psychical shock and not a result of the physical injury; that the best key to the solution of the peculiar combination of symptoms was a *cerebrospinal disassociation*; that normally the brain superconsciously or subconsciously controlled in a measure the functions of the cord, regulated them, so to speak, perhaps roughly speaking, like the governor of an engine, and that when in some occult way, this control was disturbed, the cord acted tumultuously or irregularly with all the train of characteristic symptoms, aboulia, amnesia, over- and irregularly-contracted muscles, anesthetics, hyperesthesias, fugitive and irregular pains, increased reflexes, etc., etc. I also stated that the large majority of these cases eventually recovered, in proportion to the more favorable conditions of life and life-history and constitutional status of the patient; that a certain proportion only improved; and, finally, a small proportion were permanently injured and went from bad to worse.

At present writing ten months have gone by since the trial of this case. It will be interesting to note the man's present condition. He is now living in the country doing light work about the house. He can carry a pail of water; but he cannot lift it up the two or three steps into the house unless he first steps up and draws it up. His attitude and gait are the same. On the scales in my office he has gained eight pounds. There is the same rigidity of the back muscles, the same tenderness over the spine; the same pupillary reflex, the same rapid pulse. He reports himself just the same, barring the increase in weight. I present a photograph of him stripped, standing in his usual attitude with his stick. This attitude and gait have not changed since I first met him and I have seen him repeatedly on the street.

In the rebuttal, a disinterested physician, in good standing, was called in, who had examined the plaintiff in my office, and who, unprompted by me, had noticed at once the unusual and exaggerated pupillary reflex and the accelerated pulse, both following pressure over the lower dorsal spine, as well as the pronounced hemianesthesia; he, too, testified to the genuineness of the neurosis.

When the case went to the jury there was only one question in their minds, namely, the amount they should give the plaintiff. Several were for large sums. I understand there was one man against this view. The fact that there was one

man on the jury who would so act was hinted to me by two men who know juries pretty well. At any rate a verdict was soon given for \$9,500.

I have had some dealings with this railroad in question before this case. I have been called on a number of times to make x-rays for the Road. I have also appeared for the plaintiff in a number of damage suits against this Road. Some three or four years ago I was called to attend a man who fell from a car from the giving way of a grab-iron very much like the imagined accident in the trick case, only the man fell on his left side and ruptured his spleen. There was a violent intraabdominal hemorrhage. I removed the spleen, but lost

ical witness in the courts. Several corporations are employing me for my x-ray work, yet I am more frequently employed by the plaintiff in the damage suits against these very corporations, the regular corporation surgeons appearing for the defendant.

The lawyers who were employed in this case are really corporation lawyers, and I imagine that nine out of ten of their cases are for this corporation, and I have appeared in court mostly for the plaintiff against them, and yet they call on me frequently when they represent a plaintiff and have also employed me for their own corporation, as an expert medical witness. That I had the good opinion of this firm was gratifying to me.

The attorneys for the defendant in this case made two great mistakes. In the first place, they employed deceit and fraud as a weapon against one who, at least, had the reputation of decency and respectability, and where they could only prove that he could be deceived by a hired impostor on one examination, which they had cunningly planned to make as short as possible. Anybody can be deceived if the proper means are used. Deceit is always a dangerous weapon no matter how skillfully employed. As far back as man has recorded his thoughts he has so expressed it. Camerarius put it well in a famous sentence: "*Nulli fraus tuta latebris*," where the word *latebris* is a whole sentence in itself—Deceit is safe for no man *though he hide in secret places*. Counsel for the defense had the ponderously difficult task of explaining to the jury why his client had to lie and cheat to defend himself. Secondly, they compared my case of deception, one examined but once and hurriedly in my office, with nothing verified or corroborated, and with no possibility of coming to trial, with another case, seen by me four times and treated and examined by other physicians, and all the details of the accident corroborated by witnesses, and regularly brought to trial. I was deceived in one, and, therefore, I was deceived in the other; and they attempted to drive this *non sequitur* home by getting five medical witnesses to testify along the same line. To compare two such cases and to try to influence twelve men of ordinary intelligence would in itself constitute a fraud were it not so stupid on the face of it. It was only the hired impostor who showed intelligence; the defendant alone made himself ridiculous.

One of the physicians in the case twitted me for taking a contingent fee, and a modest fixed fee at that. He himself had asked more as a "flat fee" for testifying, even before he saw the plaintiff, and yet he took the position that I was the one who must be biased and not himself; and that the contingent fee is not professional. I have never asked nor received more than \$100 for being retained in any case, no matter what the verdict was, and I consider it a modest fee. I am supposed to see the case at varying intervals for months, besides testifying in the court. When a patient is sent to me for examination my position is an absolutely independent one. If I see no injury and no reason for suit I can so state and can decline to have anything to do with the case. This not very infrequently happens, and usually my decision holds. I feel I am delightfully independent, and much more so than when retained by a corporation; then I feel I am in a sort of straight-jacket. This may be from testifying so much more for the plaintiff, and that my sympathies are with the man with the dinner pail rather than with the high official. Viewed from

my patient, despite all my efforts. The mother brought suit and it was settled out of court.

Again, five months ago, the claim agent of the same road asked me in consultation with another physician to examine a man injured while in the employ of the Road. I found serious injuries; in fact, the man was a hopeless cripple, and I advised a settlement. The very next day the man's attorneys called on me for information about the case, which, of course, I had to decline to give on the ground of being employed by the other side. The case was settled for a mere nominal sum.

On account of having done much x-ray work I have been more and more called upon to examine and give an opinion on railway and other injuries, so that I have more and more been retained as a med-

every point of reason, and admitting that we are all biased to a certain extent, I believe I have the advantage as a free lance. I can see nothing wrong in the contingent fee provided it is a reasonable one and not based on any percentage. In private practice we are not infrequently paid on this principle. It is the only one for the poor man who does not wish to be on charity, and whose gratitude for services rendered prompts him to pay for these services when he has the means to do so. I believe it is quite universally done, and that there is nothing in our code of ethics prohibiting it.

As the question of bias and self-interest is such an important one in medicolegal testimony I beg to call attention to a paper of mine which appeared in the *Southern Medical Journal* for August, 1908, entitled "A Medicolegal Case Involving X-ray Testimony and Its Bearing on a Recent Proposal to Regulate Medical Expert Testimony." In that paper I quoted a proposal to regulate medical expert testimony published in the *MEDICAL RECORD* for May 9, 1908, which read as follows:

"The committee of the Medical Society of the State of New York appointed to confer with a special committee of the New York State Bar Association in regard to the regulation of expert testimony has prepared the following tentative draft of a bill with this end in view: 'At any time in the pendency of any civil proceeding in any court in which any medical or surgical question is likely to be material, the court or any justice thereof may, or at the request of either party, shall appoint from the list made up as hereinafter provided one or more persons learned in the science of medicine and surgery, and of not less than seven years' actual practice as official experts, who shall investigate the facts of the case and give their opinion upon any such question arising in such proceedings, and make written report thereof to the court. Upon such appointment by the court, or if the parties file an agreement designating an expert for the case, the court shall issue an order for the person so appointed or agreed upon, to be served in the manner provided by law for the service of subpoenas. As soon as may be after service thereof the expert shall make such examination of the case as in his judgment may be necessary and practicable and shall file his report as above provided. Such report shall be filed in the case and shall thereupon be open to the inspection of either party, and such report may be read in evidence, and such expert may be called as a witness by either party at the trial. The New York Academy of Medicine for New York City and the Medical Society of the State of New York, acting for the State outside of New York City, shall through committees appointed by these organizations furnish to the court or courts in various counties, a list of names of members of the medical profession of good standing, and of not less than seven years actual practice, recommended by them as competent and expert in medicine and surgery, from which list the court may select such expert or experts as in its judgment may be required. Such official expert shall be paid out of the treasury of the county a minimum fee of \$50 for the examination of, and report on, any case in question; \$50 additional for the first day's attendance in court upon the case, and \$100 a day thereafter while attendance is required by the court. The expert witnesses so listed may be called by any court of the State, and if called from the county of their residence the fee shall be increased to the extent of

the extra expense incurred to which shall be added a reasonable compensation for such extraordinary service and loss of time. Either party at the trial may call other expert witnesses than those appointed or agreed upon, but at his own expense.'"

This proposal impressed me as a step in the right direction. I had hoped that there might be further developments along this line, but I have seen nothing of it.

I also attempted to bring out in this paper the bias shown by the medical witnesses for the defendant. Briefly, the plaintiff sustained an injury of his right elbow, followed by some restricted movement in the joint. I made several x-rays of the injured limb and also of the normal side for comparison, and found a fracture through the lower end of the humerus, running into the joint. The evidence was unmistakable in black and white. The company's surgeon denied any injury whatsoever, and the lawyers for the defense, seeing the case going against them, hurriedly brought in two other corporation surgeons to help out. The plaintiff was hurriedly examined in the middle of the trial, as well as my plates, and they both testified that my plates showed nothing. Now I know these men to be honest men, and I also know they were influenced by the crassest bias. The man, however, got a verdict of \$677.65. I examined the joint two years after the trial, and again but a month ago, and found the same restricted motion. My experience has taught me that the chief error of the defense in these damage suits, which is based, of course, upon the statements of the corporation surgeon, is that they deny too much. This places one in a very awkward position, for it gives an added weapon and advantage to the other side. "*Omnia dat qui justa negat*," a sentence ascribed to the Latin poet Lucanus, who, whatever his poetic qualities may have been, was a smart fellow withal. In a recent damage suit where the plaintiff had sustained an initial injury of considerable physical violence, and where the psychological shock must have been very great, for the victim for several seconds could see the oncoming blow from which escape was impossible, and who developed a condition quite similar to the plaintiff's in the present case, counsel for the defense began his declaration to the jury somewhat in these words: "Gentlemen of the Jury: We propose to show you that the plaintiff in this case was in no way seriously hurt; that there is at present no evidence whatsoever of his injury, that he only had a nervous shock, and that his present complaints are imaginary; that in short there is nothing the matter with him." Now this was a very stupid thing to say, and the corporation surgeon who advised him in the case gave him very bad advice. He played absolutely into the hands of the other side, and counsel for the plaintiff made good use of his opportunity. Throughout the trial it was very evident that the defense had no idea what psychological or mental might mean. His only idea was that psychological was nothing, no thing, and therefore negligible, while opposing counsel fully realized that a psychological change was still a material change, although we were as yet unable to put our finger on it; that everything had to be argued on a basis of a materiality of some kind. And this led him to show that the psychological by the very fact of its being elusive and indefinite is more difficult to treat than the ordinary physical injury; that the severe physical injury may be more easily cured than an apparently simple psychological trouble.

A mere glance at the figures of damages paid by corporations startles one with its stupendousness; one can hardly realize the toll paid for modern rapid transit. One wonders a corporation can live at all; dividends seem impossible. With the ever increasing rapidity and intricacy of this transportation, the dangers should increase in geometrical rather than in arithmetical proportion, according to the laws of physics. Under present laws and conditions a point must be reached where continuation is suicide. Whatever change must come, must come through the law. On one point at least a step can be taken, and that is, a more careful consideration of the initial injury, and the conditions and circumstances existing at the time. This factor has always been an important one in my estimate of the real damage done, and the prognosis as well.

I have seen cases tried where the initial injury was so ridiculously slight that no corporation or individual could in any way have been held accountable, and yet damages were recovered. A certain latitude is due the defendant. We do know that psychical disturbances come from apparently slight causes. But it becomes at once evident that the susceptibility to psychical change must have been very great, so great, indeed, that the victim was a subject for treatment before the accident, and that the ordinary occurrences of every day life were equally liable to start the new train of symptoms—the sudden attack of a barking dog, the slamming of a door, the pricking of a finger, insignificant accidents, which Janet* has so well shown to be operative in hysterical attacks and other mental states. Such cases in court should never be argued past the initial injury; they should never get to the court room. The present law that “the existence of a predisposition does not excuse the defendant” will, by necessity, have to be modified.

Again, the law “that the defendant is not excused from the results arising from malpractice on the part of the plaintiff's physician” does not seem to me just. Certainly if malpractice on the part of the corporation's surgeon can be shown, it is bound to influence the verdict. I recall one case where a desperate effort was made by the defendant to show improper treatment on the part of the plaintiff's surgeon, where, from my standpoint, the defendant's surgeon was distinctly to blame in the original treatment.

As already mentioned, the attitude of the defendant's surgeon is by no means always conducive to his employer's interests. Holding the position of a regularly employed servant of the company, and expected to stand by the company, he is in constant danger of going too far in the support of his client. He has lost the faculty of putting himself in the other man's place, which is usually a very necessary thing to do, to get an unbiased and judicial view of the case. The great principle of charity rests on this faculty. Certainly, in denying too much he injures his cause, and this fault can partly be explained by the lack of this faculty. Again, I am convinced that a lack of the proper conception of the psychology of hysteria and its allied nervous states, the cases which are the most stubbornly

contested, and with the bitterest feelings aroused, favors this wet-blanket denial where nothing is seen but exaggeration and fraud; they show a sublime indifference to trauma.

With all the brilliant symptomatology of Charcot, it was Janet, the brilliant French psychologist, who helped put these symptoms into line, and give us a more comprehensive, a more intimate, and a more charitable view of these cases. And Janet's conception has been maintained and further elaborated by subsequent workers, so that there is no excuse for a failing to apply this new knowledge. But the railroad surgeon says, and quite naturally: “But this is out of my line; this belongs to the nerve specialist, the neurologist.” Quite true; but the railroad then had better get the services of such an expert where testimony might enlighten the jury, and possibly protect the defendant. He certainly could be of more benefit than the rushing into the case of five surgeons who are quite willing to deny everything in spite of all consequences.

But as a skilled lawyer and a very excellent judge of human nature said to me after the trial of this case: “It's great sport, even if it is a free fight, and I am always intensely interested.”

10 JONES STREET, W.

POLLEN THERAPY IN POLLINOSIS;

WITH RESULTS OF TREATMENT BY IMMUNIZATION METHODS DURING 1915.

By SEYMOUR OPPENHEIMER, M.D.,

AND

MARK J. GOTTLIEB, M.D.,

NEW YORK

THE term “hay fever,” although it has received almost universal adoption, is a misnomer, covering as it does all the forms of periodical influenzas. We use it only in its most generic sense. Our preference would be pollinosis or pollen disease. Although not dangerous to life, it causes at certain times such extreme discomfort to some of its victims as to unfit them for their ordinary pursuits. While it is possibly among the minor ills that flesh is heir to, a prominent place must be assigned to this curious infirmity. If we accept the view that it is a disease of the classes rather than the masses we may take the viewpoint of self-congratulation rather than of humiliation as indicating a superiority in culture and civilization of the favored few. When this idea of the intimate connection of pollinosis and culture has been firmly grasped by the public mind, the complaint will perhaps come to be looked upon like gout, as a sign of breeding. It will be assumed by those who have it not—like Louis the Fourteenth's courtiers who submitted their sound flesh to the surgeon's knife in pious imitation of their majestic but diseased master. Soon, no doubt, presence or absence of the tendency to sneeze at the sight of a rose will become a test surer than the letter “h” for the separation of the elect from the common herd.

To speak more seriously, however, the prospect opened up by modern observation is rather alarming. As civilization and culture advance, other diseases analogous to the one under consideration may be developed from oversensitiveness to sound, color, or form, and the man of the twenty-first or twenty-second century may be a being of pure intellect,

**État mental des Hystériques: les accidents mentaux.* Par Pierre Janet. Paris, 1894, or the English translation: *The Mental State of Hystericals; A Study of Mental Stigmata and Mental Accidents.* By Pierre Janet, Litt. D., M.D., with a preface by Professor J. M. Charcot, translated by Caroline Rollin Carson. G. P. Putnam's Sons, New York, 1903.

whose organization of mere nervous pulp would be shattered by a strong emotion, like a pumpkin filled with dynamite. Perhaps, however, in that dreary time of omniscience to which we are all said to be hastening, when machinery shall have taken the place of nature, and nothing is left to remind the world of flowers but dried specimens in botanical museum, the disease will become extinct equally with the cause. At the present time we are fortunately still far removed from this consummation and the human is warmly interested in devising means of curing the disease.

Hay fever, or pollinosis, is a disease which manifests itself in the spring, from the early part of May or June to early or middle July, and in the autumn from the middle of August to the end of September or early October. It is characterized by itching of the eyes and lacrymation, sneezing, seromucous discharge from the nose, obstructed breathing, and itching of the palate and face. If the attack is very severe, sooner or later there are coughing and difficult breathing accompanied by wheezing. Pollinosis is caused by the action of the pollen grains from flowering plants, the pollen being carried by air currents and thus conveyed to the mucous membranes of the eyes, nose, and the remainder of the respiratory system. If the recipient is susceptible to any of the pollens which occur in the air and if their concentration is sufficient to go beyond the threshold of reaction, an attack of pollen disease will promptly ensue.

The term rose fever as applied to the spring variety of pollen disease is also a misnomer, because in a large series of cases of vernal pollen disease tested by us we have found only one person who was sensitive to the pollen of roses. To be correct, one should speak then of the spring type and fall type of pollinosis. The impression of the patient as to the causative pollens cannot in most instances be depended upon. In many instances patients have made the suggestion of the most unique pollens as being responsible for their attacks, but upon investigation this was proven to be a faulty observation in the majority of cases.

Etiology.—Predisposing Causes. Heredity plays a very important role in the etiology of pollen disease, as we have shown that over 90 per cent. of our patients have other members of their family who suffer with allied ailments such as urticaria, asthma or other manifestations of anaphylaxis, following the ingestion of casein, egg white, shellfish, or are sensitive to the contents of pollen, flies, or are anaphylactic to dust, the serum of horses, and cats.

Any denuded surface on the body is a suitable place for the parenteral absorption of the proteins of pollen, so that given a patient whose antecedents either in collateral or direct line have shown themselves to be sensitive to any of the above-mentioned substances; that patient, if so exposed, will in all likelihood develop pollen anaphylaxis. For the above reason it can be easily understood why chronic inflammatory conditions of the nose and throat, such as sinusitis, or obstructions to drainage make these organs a suitable place for the reception of this disease. The nasal factor, however, should not be considered as too important; in fact, many of the patients under our care have had considerable surgical treatment of the nose at previous times in the hope of the relief of the condition and it has been in but the rarest instance that benefit has resulted. While it is important that a

marked stenosis or mechanical condition causing definite pressure or a suppurative process in the accessory nasal cavities should be corrected, yet to attack every slight septal irregularity or other deviation from the normal by surgical means is in our judgment a procedure which should not be countenanced.

Exciting Cause.—The cause of this disease has definitely and conclusively been proven to be the pollen of anemophilous plants, particularly the Gramineæ, Cyperaceæ, and Compositæ.

In a previous communication we have enumerated a large variety of pollens which we have found active and which our botanists have been engaged in the collection of. The collection work is most important, and considerable experience has been gained as to the best means of conducting this work. Some grasses and plants were found to be best brushed in the fields, whereas others have to be subjected to a variety of other methods to obtain the best results.

In order to carry out this work in the most satisfactory way it is desirable to have as large a working collection of pollens as possible, so as to be able to treat patients coming from distant points with the particular pollen of the grass or plants which grow abundantly in the locality in which the individual patient lives and is exposed to and to which he is susceptible.

The method of preparation of the pollen extract we have dealt with in a previous report. At the present time our laboratory staff is engaged in a large series of experiments for determining what relation exists between different methods of pollen extraction and their solution or suspension and the degree of immunity induced.

It is possible to produce a typical attack of pollen disease in a sensitive individual at any time of the year independent of the time when the plants bloom to which the patient is sensitive. A small quantity of pollen, if aspirated into the nose, will cause a typical attack of pollinosis which will last for a few hours, and if the quantity sniffed up is very large, a severe attack of anaphylaxis may result.

Diagnosis.—Three methods may be employed for determining to which pollen a patient is anaphylactic—the ocular, the hypodermic, or the cutaneous method. The method which we now use for determining which pollen or pollens are operative in a given case is the skin scarification or cutaneous method. A very small scratch, not enough to produce bleeding but sufficient to cause the exudation of serum, is made on the arm of the individual to be tested, and a very minute quantity of pure pollen is gently rubbed into this wound. In a very few minutes a wheal will develop around this area of scarification. The swelling and redness are measured after fifteen minutes has elapsed; subsequently such vaccinations are made during the course of treatment, and are again measured after a fifteen-minute period, so as to determine whether the size of the wheal diminishes as treatment and immunization progress.

Some patients are susceptible to only one or two pollens and there are other patients who suffer from a sensitiveness to all pollens, so that the latter have symptoms of pollinosis lasting five months during the spring and summer, while the former exhibit symptoms but from six weeks to two months. It is important to bear in mind that in the case of a patient showing symptoms, let us say by way of example, from May 15 to July 15, the symptoms

are not due to a single pollen, but rather the attack is kept up by a succession of different pollinizing periods of the different plants which are operative in the given case. It is important for this reason to learn from the botanist working in the fields when each grass begins and terminates its pollinization so as to determine the period of the beginning and the ending of the proposed immunization to the individual pollen. The earliest we have found a patient suffering from pollen disease in this locality is about the first of May. This spring, however, we had a patient under our care whose attack of pollinosis began in the early part of April. He is a resident of southern Georgia and is sensitive to the pollen of the pecan tree. The latest we have known patients to suffer from pollen anaphylaxis is the latter part of October. This occurred in several patients suffering from the fall variety of pollen disease who removed to an immune locality during August and September, and on returning in October, developed symptoms of pollen anaphylaxis because they had not developed their usual seasonal immunization and were just as sensitive in October as they were in the early part of August.

In conjunction with the scarification method of diagnosing which pollen is operative we have made extensive use this year of the complement fixation test of the patient's blood, using an antigen of the pollen which gives the most intense reaction. In that way we are able to gage how much natural immunity exists. After ten or twelve treatments the complement fixation test is again performed to determine the amount of immunity produced. In this way we are able to judge when treatment should be stopped. It has been our experience that pollinosis patients who have never had treatment show a doubtful fixation test, whereas those who have had treatment the previous year show a reaction of between three and four plus. From this it can be deduced that a patient having had treatment the year previous carries over a certain degree of immunity to the ensuing year. This is important in its practical bearing on the duration of seasonal treatment required.

Complications.—Notwithstanding the fact that the subject of pollinosis has never been taken sufficiently seriously by the profession and general public, it nevertheless has its serious aspects. A case of pollinosis may develop a train of symptoms which, if remaining untreated, may be the cause of an untimely death.

One of the most common complications is asthma. Patients suffering with pollinosis, especially those who breathe through the mouth, due to obstructed nasal passages, inhale into their bronchial tubes large quantities of pollen which cause a swelling of the mucous membranes of the lower respiratory tract, with the production of typical asthma. Superimposed upon this, should the patient be unfortunate enough to have his bronchial mucous membranes infected by any of the microorganisms which are natural inhabitants of the respiratory tract, such as streptococci, pneumococci, etc., asthmatic symptoms are perpetuated throughout the year with an accompanying profuse bronchorrhea. The asthma and bronchitis are very much worse during the time the patient is exposed to the pollen disease, and the conditions are as pitiful as any that the physician has to contend with. Ultimately the pulmonary tissue becomes dilated and emphysema, followed by the usual cardiac dilatation, may ensue.

Nasal sinusitis occurs very often during an at-

tack of pollinosis, due to retention of secretions from obstructed drainage of the sinuses, and deafness due to tubal catarrh or pressure upon the membrana tympani during violent paroxysms of sneezing is a very common complication and sequel of this disease.

Prognosis.—A great many cases of pollen disease have their attacks each year without acquiring any of the complications or sequelæ referred to. In fact, we have seen patients who have suffered with this disease for over forty years, and with the advent of age the intensity of their attacks have gradually diminished so that they are moderately comfortable during the season for pollen anaphylaxis. On the other hand, we have seen severe pollinosis accompanied by asthma and bronchitis followed by chronic emphysema and myocarditis. It is our firm conviction that every case of pollen disease, either complicated or uncomplicated, except where degenerative changes have taken place in the pulmonary or cardiac tissue, can be benefited, if not cured, if we are in possession of the pollens which are instrumental in the causing of symptoms in the given case. The cases which have superimposed on the primary condition an infective bronchitis do often very well, if an autogenous vaccine from the pathogenic microorganisms found in the sputum is administered in conjunction with the specific pollen antigen. The outlook depends in a great measure upon the general condition of the patient. Many patients come to us very much below weight, with an anemia or other physical incapacity, and if this is not corrected by proper medication, diet, or other measures, the treatment will be a failure, because they are unable to produce for themselves an immunity.

Treatment.—We have referred in our previous writings to the principles underlying the basis of all immunization methods, and these same methods which have proven so successful in bacterial conditions, it is our belief, can be applied to a non-bacterial factor.

We recognize two different immunization methods, active and passive. By active immunization we mean an immunity which is developed in the individual himself, and by passive immunization an immunity which is transferred from an animal to a human being or from one human being to another.

Active Immunization.—It is our practice to begin treatment about eight or ten weeks before the expected onset of symptoms. Gradually increasing doses of pollen extract are given about every four to six days; should an immoderate swelling and itching occur at the site of the injection, the dose is lowered or remains the same until no more reaction occurs to that dose, and then we proceed increasing the dose as before. If a patient is susceptible to more than one pollen, an individual injection of each is given so as to gage the dose of each pollen and thus vary it according to the reaction produced by the previous injection. Under these circumstances we have been compelled to give to some of our patients five or six hypodermic injections at each treatment. These directions as to treatment are, of course, subject to much modification in each case and can be construed only in the most general way. Much judgment must be employed in securing an accurate dosage, as this is all important in its bearing on the results. Our observation has been that an excessive dosage will break down the potential resistance of the patient and defeat the object which we strive to obtain.

Passive Immunization.—Should any of our patients not be able to develop for themselves enough immune body as would be expected from the effect of the injections of pollen extract, one large dose of blood serum is administered from a rabbit that has had large quantities of pollen extract injected at regular intervals for about five months. Under these circumstances the rabbit serum shows an antitoxic content of thousands of units which are sufficient to bind the antigen with the complement in the blood and thus effect a quick proteolysis of the antigen down to amino acids and ammonia, which are not toxic. Only one dose of this serum is given and thus the possibilities of anaphylaxis occurring are avoided.

Many of the patients who have come to us during the attack of pollen disease have felt greatly improved within a number of hours after the first treatment. About all of the patients in this group stated that their symptoms were decidedly modified by each treatment. It has been observed if treatment is kept up regularly at the proper intervals, the symptoms disappear entirely. Should the patient's vitality be insufficient to build up for himself an immunity, we administer a large dose of immune serum, as stated above, and our results for this procedure have been most satisfactory.

Results.—Spring Cases. In our published reports in 1913-1914 we had the gratification of having 50 per cent. of seasonal cures. After much refinement in our method of pollen collection, extraction, suspension, etc., and the experience gathered from our previous year's work, we are able to state that of the thirty-two cases of spring pollinosis (1915) which we had under our care, only two had symptoms. Some few patients exhibited symptoms of but a few moments' duration and of the mildest intensity, and can be construed as having been satisfactorily immunized. In one case we have not been able to determine the pollen to which the patient reacted markedly, and treatment with the pollens to which he was but mildly anaphylactic has been conducted very irregularly.

Fall Cases (1915).—Eighty-five patients were subjected to diagnostic tests, the detailed report of which in connection with the report of the thirty-two spring cases tested will be taken up in a subsequent communication.

Of these eighty-five patients, sixty-two took up treatment. These latter cases can be divided into two groups, the one comprising fifty-two cases in which treatment was begun sufficiently in advance of the attacks to have made the immunization possible. The other group comprises those who consulted us either during their attacks or but very shortly in advance of the expected attacks. Of the first group of fifty-two, fifteen were definitely free from symptoms, twenty-five were markedly improved (this being the direct expression of opinion of the patient), and twelve had their symptoms apparently in no way modified by the treatment, although it appeared that the attack took place rather later than in previous years.

Of the second group of ten, in four the attack was decidedly beneficially influenced after but one or two injections.

Conclusion.—The authors feel it incumbent upon them to warn the medical profession against "hay fever" vaccines which contain a mixture of a large number of pollen extracts, such mixture being given both for spring and fall cases. No diagnostic means are employed to determine which pollen or

pollens are operative in a given case. Under these conditions many a patient who is suffering from the spring variety of pollinosis, being already a fit subject for further sensitization, is placed in danger of becoming sensitized to those pollens which are active during the fall. It may also be stated that pollen extracts in large doses are extremely dangerous, and with the dosage not properly controlled by experienced workers in this particular field, a calamity from mishandling may cast a shadow upon a very valuable proposition.

We speak in emphatic terms upon this subject because in our experience we have seen the ill effects of large doses of these substances and appreciate their dangers; therefore, this note of warning.

In conclusion let us express the hope that our readers have not alone been interested in the subject we have presented, but that they have been impressed with the honesty and earnestness of the manner with which work has been conducted, and it is our hope that at least a fair proportion of those patients who are under our care will have their symptoms so improved that they will no longer have occasion "to fear the gracious odors conveyed upon the gentle wing of some calm breathing wind."

45 EAST SIXTIETH STREET

FLATULENCE AND METEORISM AND THEIR TREATMENT.*

BY MAX EINHORN, M.D.

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL AND HOSPITAL.

A GREAT many patients with digestive disorders complain principally of the belching of gas and a feeling of fullness; others, of flatulence and the passing of wind per rectum, which annoys them a great deal. By flatulence we usually understand that type of gas accumulation which exists in the stomach or lower down in the digestive tract, but which is easily liberated. The patient can get rid of the gas easily by belching or the passing of wind, flatus. He may feel a little pressure, but has no difficulty in getting rid of the gas.

By meteorism, on the other hand, we understand an accumulation of gas in the stomach or intestine which is not easily gotten rid of. The great difficulty of the patient consists not in belching or passing wind, but in the fact that he cannot do it. It is a kind of incarcerated condition of the gas.

Usually the variety which has to deal with flatulence will give a better prognosis than the second, which is not so easy to correct.

Beginning with the patients who suffer from flatulence, we have to deal with a difficulty of the stomach. They complain of eructations of gas from the stomach, and that they have to belch a great deal. This is a very common variety, and embraces a great many dyspeptic patients. Some of them have no other symptoms outside of the gas difficulty and the requirement of ridding themselves of the gas, and they complain of nothing else. The patient feels well and looks well, but is annoyed by having to belch constantly, and sometimes he cannot go to an entertainment or other gathering on account of the annoyance to himself and to other persons. Others complain that it interferes with their business.

In other patients the same type exists, but with

*Delivered at the N. Y. Postgraduate Medical School, on December 31, 1915.

the addition of a feeling of fullness, and loss of appetite; and sometimes the regurgitation of food, slight pains, constipation, and other symptoms. Years ago physicians were inclined to ascribe all the symptoms to the accumulation of gas. They considered the type of disease accompanied by eructations as very grave, and clinicians thought the gas must be due to the fermentation going on in the digestive tract, and especially if the carbohydrates were not digested they called it amylaceous dyspepsia. Dujardin Beaumetz described this type some thirty or forty years ago, in his book on the stomach and intestines, in a chapter on fermentative dyspepsia dealing especially with these troubles.

Now while there are conditions in which fermentative disturbances exist and the gas may be due to that cause, still the majority of patients complaining of eructations, etc., do not suffer from that type. What is it, then, that is belched up, if it is not a fermentative process that does it? To what can we ascribe the accumulation of gas?

The answer is (1) that there may be some disturbance in the absorption, and (2) that there may be a great amount of gas production or gas ingestion. The patients who belch and suffer from it can do it all the time. There is no end to the belching, and the stomach is in the same condition, *i.e.* not much inflated before or after the eructation; the patients do not even feel relieved after the act of belching.

Dr. Bouveret of Lyons, France, was the first to assume that in most of these cases the eructations were due not to an increase of gas in the stomach, but to the swallowing of air. The more the patients belch the more they have to do it, for after belching they swallow more air and have to belch it out again. This he called aerophagia, "the eating of air," and he was certainly correct—that means for the majority of cases. In these there is no organic lesion present. . . . I would call it an idiopathic type of eructation. Then the stomach may be perfectly right; it is a kind of habit which the patient has acquired—to bring up gas—he thinks he has to do it.

When he has performed it frequently the cardia is relaxed and ready to do that act of letting the gas out, and the stomach does not want to do the absorbing. Whenever there is lessened pressure in the organ there is less absorption. In these instances, while the stomach may be perfectly normal there is after a while disturbed absorption due to the relaxation and lessened pressure, and the patient will never get better while that continues.

In contradistinction to this variety of aerophagia, or eructation of gas, there are conditions encountered in which there is a really increased fermentation going on in the stomach. But here the patients rarely complain of belching. According to my experience, the amount of gas emitted is due to just the opposite of what was formerly believed. If we consider the type of disease in which the pylorus is obstructed, with the food fermenting in the stomach—*isochymia*—the food never entirely passes into the intestine, and there is always a fermentation going on in the stomach—we notice that in this type of gas augmentation the patients complain of pain and acid vomiting, but not of constant belching. They may occasionally bring up a little gas, but it is quite a different type, that fermentative condition. There is an amount of badly smelling gas developing all the time. When this gas is kept in the stomach it irritates the cardia, which then remains closed

tighter than normally, and the patient cannot bring it up, and only suffers pain and discomfort—just the opposite of the other variety, where there is constant belching, no pain, and no odor to the gas.

I have often been astonished to find in patients who have a cancer of the pylorus,—where the food cannot escape the pylorus and there is much fermentation and decomposition, so that after introducing the stomach tube there is such a disagreeable smell that one can hardly stand it in the room,—that the patients would be utterly unaware of that condition. It is an exception that the patient is aware of the bad odor. How can that be explained? The answer is the same as before. In these conditions the cardia is almost hermetically closed and the gas cannot reach the mouth, and the patient is unconscious of the condition. You may think that nature has arranged this wisely for the patient, and it is well for the patient in one respect, for he would be in a most distressful state if he were aware all the time of this decomposed matter in his stomach.

It is important to note the great difference in these two conditions. They show that, clinically, the fermentative conditions have not much to do with aerophagia, or nervous eructations.

Now a few points with regard to the treatment of these conditions. The treatment of aerophagia will consist simply of suppressing the coming up of the gas. These patients must be told not to bring up the gas, but rather to suppress it. Many patients think the gas exists in the stomach, and they bring it up in order to feel better, and they try to belch, and some physicians encourage that opinion. These patients will go on all the time that way unless they are corrected. It is important for them to know that the gas should not be brought up. The second point is of still greater importance: these patients should not be put on a diet. A great many physicians, even now, believe that all these troubles are due to fermentative troubles, and will forbid the patients many foods, will take away bread and carbohydrates. Now if these patients are put on a diet and suffer from too great uniformity and lack of food, they really become sick—not because of the food, but because of the want of it. They should not be dieted, but should be allowed a liberal amount of food, like every one else. They should have no restrictions at all. Another point of treatment would be the administering of some sedative, because these people are usually of a neurotic type. If you tell them not to bring up the gas they cannot at once break the habit, but if you give them a mild sedative, valerian, or a bromide, etc., they are accessible to the suggestion, and if you go on wisely with the nerve remedy you can a little later take it away and they can do without it; they have gained confidence. All of these patients give a good prognosis, and can be easily cured.

In the second variety, in which the eructations are combined with some complicating disease, such as gastric catarrh, gastrosuccorrea, hyperchlorhydria, etc., which give rise to amylaceous dyspepsia, the treatment will be that of the original disease, and besides, if there is more starch remaining unconverted, you will have to regulate it. Amylaceous dyspepsia has played a very important part in past years, and is now called hyperchlorhydria. I am of the opinion that none of these patients should be dieted too much. Many physicians think that the carbohydrates should be taken away from them, but I am not of that opinion. Either you can partly

restrict starchy food, or you can give remedies that change the character of the starchy food—alkalies, etc., which diminish the acidity and disastase. That is the main thing. That is better than to take away the starchy food.

Now we will consider the type of flatulence which has to do with the intestine. Here we find similar conditions and slight pain: that means a great deal of gas is passing out in the form of flatus, and such a patient sometimes never gets freed; he keeps on passing and passing wind. How is it with that gas?

Here, also, are two conditions present; one in which the gas formation or emission of gas continues without other disturbance; the digestive act is correct, and everything seems normal; and another kind in which there is a complication in the digestive tract. Two types: The one in which nothing wrong is found in the digestive tract, must be explained by diminished absorption of gas, just as in the stomach. There is always formation of gas in the intestine, or the food could not be digested. Gas is always formed by the act of digestion, but normally it is absorbed and goes into the blood, etc., and is changed into different components. If everything is normal we are unconscious of anything, and the gas is quickly absorbed and does not give rise to any symptoms.

But suppose the gas is formed in the same way, but that the absorption is disturbed; then something will happen. Now in the lower part of the digestive tract, in the colon, there are more gases forming from bacterial action and decomposition, etc. Some are of the opinion that almost one-third of the fecal matter is due to bacteria. There are always decomposing processes going on, and gases all the time present, but they are absorbed so quickly and changed into innocuous bodies for the organism, and we do not notice them. It is only when a movement comes and the gas goes first and clears the way that we pass flatus. That is a provision of nature, to widen the intestinal canal and have it ready for the passage of the feces, but that amount could be absorbed if necessary.

Now, then, there are always gases in the colon; if a patient passes flatus, he relaxes his sphincter, and there is diminished pressure on the colon; at that time the gas is not so quickly absorbed; if he feels like doing it again, very soon he can push out another amount of gas. Rosenheim explained the frequent passing of flatus by the pumping of air into the intestine through the rectum. I do not think that is the cause. Another explanation is that there are gases all the time ready in the intestine which are ordinarily absorbed if the pressure is great enough. If the patient so desires he can relax his rectal sphincter and emit flatus. After a few moments there is more gas, which can be pushed out again. In that variety of flatus it is not necessary to do anything. If the patient knows that no harm is done by keeping in the gas; the case can be managed in the same way as the similar condition in the stomach; the patient is taught to suppress the flatus, and after a while he will feel no need to pass it. Some of these people are so annoyed that they fear to go into society; they feel they must let the gas escape, and they get nervous and sick; whereas it is simply a habit which has to be suppressed.

Some nine or ten years ago I wrote a paper on this subject, of flatulence and its treatment,* and

*Max Einhorn: On Flatulence and Its Treatment, MEDICAL RECORD, Sept. 14, 1907.

in it I said that a proof that the digestive tract can go on without sending out this gas lies in the fact that if these patients who suffer from flatulence are occupied with something interesting they go ahead and feel no need of belching or passing wind; while if they are by themselves and not very much occupied they have to do it all the time. Again, when they are sleeping it is not done; they go on sleeping seven, eight, or nine hours uninterruptedly, not bringing up any gas, and not passing wind, but as soon as they wake up they begin again. That shows that the management of gas in the organism can be left to the body; the digestive tract is fully able to take care of it, and can do so without inconvenience, but rather to the benefit of the organism, and when we are awake we should do the same. The patient should not be encouraged to allow the gas to escape, but rather to suppress it. The assurance to the patient that no harm will be done to him by the retained gas is of great importance. It is of importance to bring this point out, for one may at any time encounter patients afflicted with this trouble and may be puzzled to know how to manage it.

The second type is due to a disturbance of the intestinal functions. Here we have something more substantial to deal with. For that abnormal state we have two varieties: (1) intestinal dyspepsia due to a lack of digestion of starchy food. That variety was first described by Schmidt as fermentative or intestinal dyspepsia, and while it does not often exist we sometimes encounter it. It can be proved that that is the cause if one finds starchy food in the stool unchanged, turning blue to iodine. If the starch is left undigested, more gas is formed, mainly in the intestine. Outside of the general management this variety requires something which will remedy that particular condition—the restriction of starchy food, etc. Schmidt takes it away, but I do not. I limit the starchy food, and give the patients something for the indigestion.

Another type is due to incomplete digestion of proteins and their decomposition. This variety is more difficult to manage and the patient suffers more. This can also be determined by finding large amounts of undigested muscle fibers in the stool. In this type the restriction of albuminous or animal food is essential, and perhaps some remedy which will help the digestion, and diminish decomposition, such as salicylic acid or benzonaphthol.

There are two main points which will help in the management of flatulence: not to be afraid of gases in the stomach or intestine, and not to allow the patient to give in to the inclination to belch or pass wind, but to suppress the gas and retain it.

Before going to the subject of meteorism there is a similar condition existing to the bringing up of air which is not due to gastric or intestinal disturbance, but to some disturbance of the circulatory or respiratory or renal apparatus. It is a kind of secondary condition. For instance, a patient has a pleuritic attack, and the right side of the chest is filled with water. Then he does not get enough air. If the stomach is filled at that time the condition is worse, for that part of the lung is limited by the pressure, and cannot get enough air. If the patient eructates more gas from the stomach he gets more space, for his lung is pushed down. If the stomach is really filled with gas the patient can get much relief by sending forth this gas by belching. It is a kind of secondary condition, and the patient often tries to bring up gas in order to have more space

in his chest. Once the patient may have done this out of necessity and it gave him relief. The second time he does it, at a time when the stomach is not filled with gas, in order to try it as an experiment, and he feels better, or he imagines he feels better. Then he acquires aerophagia, just to help himself, but he deceives himself. I have been called frequently to see such patients; they complain only of gas, but there is something else; they are suffering from dyspnea. It is the same way if there is a tumor in the abdomen; it takes away some space from the lung, and the act of respiration is disturbed. In arteriosclerosis you find the same thing. So there is a secondary form of aerophagia, which has nothing to do with the digestive apparatus, as such.

Now, as to meteorism. While the prognosis of all forms of flatulence is good, in many cases of meteorism the prognosis must be given very guardedly. That means the condition may always become serious. We find meteorism or increased gas in the stomach or intestines which cannot be liberated in two conditions; one is a neurosis, due perhaps either to a spasm of some part of the intestinal tract or to a motor deficiency, paralysis; the absorption cannot go on because the mucous membrane does not work well, the muscles do not move. That may be a primary neurosis of the stomach or intestine, or a secondary condition due to some mechanical obstruction of the intestine.

One can see at once the great difference; any phase of mechanical obstruction in the intestine is very serious, but even in the neurotic form we are not certain that it will turn out well. If we are dealing with hysterical patients we can usually succeed, especially if they have had similar attacks before, but for the first time we must be on the lookout, and watch the patient, and not make too good a prognosis. For we can never tell what is coming and a fatal issue may occur without an organic lesion, if there is a paralysis of the intestine.

Five or six months ago I had a patient who complained of much distention in the abdomen and vomiting. He was a young man, about thirty-three years of age, and was quite sick. He had to be brought in from the country for treatment. On examining the vomited matter it was seen to be intestinal. I was afraid from the start that there was a very serious trouble, and had him admitted to the hospital. The next day, after washing out the stomach, we did not get good results, although we succeeded in getting his bowels to move. The vomiting went on. Several other men were called in consultation, three surgeons, and two other physicians, besides myself. I was the only one who said it was a condition of intestinal obstruction and peritonitis. The patient had no fever, and no one agreed with me. One of the surgeons said there was no peritonitis, and that the abdomen felt soft and good. I wanted the patient to be operated upon, but the surgeons were so sure that an operation was not indicated that I agreed to wait. We waited another day; the surgeons came again, and had the same opinion, and waited again; but ultimately the temperature began to rise. Then there was another consultation, and the surgeons decided to operate, because there was no other issue. I was present at the operation, but after opening the abdomen so little was found that nothing was done. I saw that the colon was filled up, but nothing was done. The patient continued to vomit, and then began to vomit

fecal matter; his abdomen quickly filled up with fluid and twenty-four hours after the operation he was dead. That was a case of paralysis of the intestine, without any mechanical lesion. Everything was examined, but nothing was found. The condition was simply due to some disturbance which I could not explain in any way; but it was there. That man could not pass wind. It was a case of meteorism. If he had been operated upon sooner, and the intestine opened, perhaps he would have been saved, but we cannot say. Anyway, these cases of meteorism are always serious.

We shall now discuss the treatment of meteorism. First, the primary form. There is no obstacle, so far as we can see. If we have to deal with a hysterical patient we may give valerian, etc., then wash out the stomach, or simply put in a tube and liberate the incarcerated gas; that sometimes gives much relief and may cure the attack. If the gas is in the intestine, irrigation may be used, a quart of water with a teaspoonful of essence of peppermint. Then, again, a rectal tube may be left in the bowel so that the gas can escape when it wants; and, third, atropine may be administered either by mouth or subcutaneously. That is one of the best remedies I know of for these spasms. Usually there is a spasm in one place and a spasm in another, and incarcerated gas in between. Atropine acts well in such conditions, and if we give 1/60 grain of atropine once or twice a day we may get good results, even in that form of meteorism which appears as a secondary condition and is due to a mechanical obstacle. Then the primary condition has to be treated, and if there is a suspicion of intestinal obstruction, invagination, or intussusception, operation should be done. Intestinal obstruction is frequently due to small growths which have occluded the intestine. All of these varieties should be treated by operation, and not allowed to go on too long. Often it is difficult to decide what the matter is, so one should be careful not to make too good a prognosis.

20 EAST SIXTY-THIRD STREET.

THE DIAGNOSIS OF GENITOURINARY TUBERCULOSIS.*

By JOHN W. CHURCHMAN, M.D.

NEW HAVEN, CONN.

PROFESSOR OF SURGERY, YALE MEDICAL SCHOOL.

THE most interesting point in connection with genitourinary tuberculosis is the question of the route taken by organisms in reaching the urine from the blood. Much experimental work has been done on this subject, the early investigations having been carried out with finely divided physical particles, like charcoal. The results of these experiments have been variable, but it is now pretty well established that the normal kidney is somewhat permeable to organisms. To establish this conclusion, however, beyond any doubt has been and will probably remain impossible, by purely experimental methods, for no experiment can be devised which is entirely above criticism; for example, the anesthetic which must necessarily be given to the animal may be held responsible for minute lesions in the kidney and, therefore, conclusions drawn from experimental animals might be attacked as indicating not the permeability of the normal, but of the abnormal kidney.

*Read at a meeting of the New York Academy of Medicine, February 3, 1916.

The two diagrams which I show of experiments I have recently made to determine whether organisms found in the urine reach it *via* the ureters or *via* the blood stream, indicate how difficult experimental study of this question is. As the first one shows, the conclusion seemed inevitable from my

FIG. 1.—Diagram showing an experiment in the guinea pig to determine the course of organisms from the circulation to the urine. The bladder has been dissected free from all connection with the body except the ureters. Organisms injected into the portal vein are readily recoverable from the urine.

early experiments that organisms injected into the portal vein reach the urine in this animal *via* the ureter; but the second figure, which indicates a control experiment, shows that such a conclusion would not have been justified on account of an error in technique, which really vitiated the first experiment. It seems altogether likely that the normal kidney is permeable for organisms, and that this permeability includes the tubercle bacillus; but this is difficult to prove absolutely.

With regard to the course of organisms in kidney and bladder lesions, there is one popular misconception which should be mentioned. It is usually overlooked that the mouth of the ureter is an extremely efficient barrier to the passage of organisms upward. In the normal bladder, as every cystoscopist knows, the ureteral orifices are not open, and it is a mistake to suppose that urine dams back readily from the bladder to the kidney. If one injects the bladder in the cadaver with fluid, the injection can be carried to the point of bladder rupture without a drop of fluid passing up the ureter. The experiments, however, of Lewin and others in the living animal have shown that during the function of the ureter itself there may be some back flow. I have recently seen a patient who died of complete urinary obstruction, and at the autopsy the bladder was found filled with bloody urine, but the ureters distended with clear urine—a positive indication of the efficient barrier offered by the ureteral meatus.

With regard to tuberculosis one can say positively that infection upward from bladder to kidney is so rare as to be excluded from consideration. The evidence for this statement is on the clinical side quite convincing, and the experimental work of Walker and others on animals has confirmed this conclusion.

The first important point to be emphasized in

the diagnosis of genitourinary tuberculosis is the fact that, contrary to a widespread notion, renal tuberculosis may occur in a person otherwise perfectly healthy. This point should be emphasized, for I am constantly seeing cases in consultation, in which the statement is made by the patient's physician that kidney tuberculosis has not been suspected because the patient is in perfectly good general health.

The second important point is that in renal tuberculosis, renal symptoms are the exception and not the rule. I have been repeatedly told by the physician that a case of cystitis could not be tuberculous because genitourinary tuberculosis was always renal, and that in this case there were no kidney symptoms. In a fairly large series of cases of kidney tuberculosis which we have had recently in the New Haven Hospital—all of them advanced cases—not a single one has given symptoms on the part of the kidney.

The third important point to emphasize is the fact that an impalpable kidney not only is no indication of the absence of renal tuberculosis, but also is no proof of the absence of an enlargement of the kidney from this disease. Here again the physician often goes astray and tells the patient that as the kidney cannot be felt it therefore is not enlarged and, consequently, not diseased. I refer, of course, to patients who are thin enough to be readily palpated, and in such patients a kidney, the site of advanced tuberculosis, may be quite impossible to feel. Specimens which I have emphasize this point. One enlarged kidney was not felt, though the patient was a thin man easily examined. On operation the kidney was found to be practically an intrathoracic organ and did not descend below the ribs. In a second case, our inability to palpate the kidney was due to the fact that the advanced tuberculosis here took the form of caseating foci, which led to

FIG. 2.—Diagram showing an experiment similar to that in Fig. 1. The circulatory connections of the bladder are intact but the ureters have been divided. Organisms injected into the portal vein reached the bladder probably from small vessels injured by the ligatures.

a great diminution in size of the organ, and it could not be felt simply because it was so small.

The sign depended upon in making the diagnosis of renal tuberculosis is, of course, the presence of tubercle bacilli in the urine. I used to speak with a good deal of confidence about the frequency with

which these organisms can be found in cases of renal tuberculosis, but I have in the last year seen three cases, all proven to be tuberculosis of the kidney by microscopic examination of the tissue removed, in none of which were we able to find tubercle bacilli in the urine. I will say, however, quite positively that this experience is rather exceptional and that in the vast majority of cases of renal and vesical tuberculosis not only can the organisms be found, but they can be found with great ease; and I am more impressed every year with the cases sent to me for diagnosis, in which this could readily have been made by the family physician if the very simple urinary examination had been made.

I have been recently much interested in the granules described by Much. Everyone who has made cultures of the tubercle bacillus is familiar with the changes which they undergo in morphology, and it has seemed probable that these morphological changes are accompanied by changes in staining characteristics. The granules described by Much are interpreted by him to represent types of the tubercle bacillus which do not possess the ordinary acid-fast character so well known. These granules were stained blue by a method which includes the use of carbol-methyl violet and a modification of the Gram stain; but they do not stain by the Ziehl method. In a case in which I have recently done a nephrectomy we were unable to find the organisms by careful search of the urine stained in the usual way. The kidney was the seat of caseating tuberculosis, the ureter was tuberculous from pelvis to bladder, and the bladder was the site of an advanced ulcerating cystitis. The urine stained for Much granules by the method recently published by Meader showed a large number of these bodies. I am, of course, unable to say exactly what the significance of the Much granules is, but I think that the study of the urine will throw an important light on this point, as we do not have here the contaminating streptococci to contend with, which were present in the sputum.

I think it is important to emphasize the fact that in the female the diagnosis of renal tuberculosis may often be made by a palpation of the lower end of the ureter *per vaginam*. I have recently seen two cases in which this sign was of vital importance, and those who are not familiar with the fact would be surprised at the readiness with which an enlarged ureter can thus be felt.

The cystoscope, of course, usually makes a positive diagnosis of this disease for us, and the cystoscopic findings in bladder and kidney tuberculosis are too well known to need mention. I may speak of one little trick which is of great value in catheterizing the ureters. Sometimes a ureter which can readily be seen cannot be catheterized because it enters the bladder at an unusual direction, and I have this year seen a number of cases in which this difficulty was overcome by passing the right catheter into the left side, and *vice versa*.

So far as the x-ray is concerned in the diagnosis of renal tuberculosis I have not found it of much value, except in one type; namely, that which is characterized by the presence of calcified nodules in the kidney. Here the shadow may indicate the diseased side when there are no other signs which point to it.

In hospital work we are not able to get a great deal of assistance in the diagnosis of renal tuberculosis from animal inoculations for the reason that a guinea pig inoculation is usually not of value

until five or six weeks have elapsed after the inoculation has been made, and I find that hospital patients cannot stay in the hospital for this period, and very often fail to report again if allowed to go home. In private practice, of course, the state of affairs is different and any doubtful case can be cleared up by animal inoculations.

With regard to treatment I think it should be emphasized for the encouragement of the general practitioner that in spite of the many difficulties met with the outlook in the surgical treatment of renal tuberculosis is extremely good. It is important to say this because I find the general practitioner rather inclined to be very pessimistic as to this disease. One extremely encouraging feature is the fact that some of the worst cases with advanced lesions do best. I have now under observation a woman who was operated on four years ago for tuberculosis of the kidney which had almost entirely destroyed the right kidney, had led to a general ulcerative cystitis, which had made life almost impossible for her, and had resulted in a very grave undermining of her general health. Nephrectomy was done and she is now, four years after the operation, in perfect health, having more than regained her normal weight and being absolutely free from all symptoms.

The most difficult cases we have to handle are those in which it is impossible to catheterize the ureters and therefore impossible to determine which side is diseased and whether the other side is actually healthy. Another difficult group includes those in which there is existing tuberculosis somewhere else in the genitourinary tract, but even of these we should not despair. I have recently removed the kidney from a patient, who four years previously had had the epididymis removed for the same disease, and he is apparently going to get well.

59 COLLEGE STREET.

FAITH-CURES.*

By J. ALLEN GILBERT, PH.D., M.D.,

PORTLAND, ORE.

THE validity of the subject of this brief paper is questioned by many. It is perfectly natural that a larger percentage of objections to such a conception should come from the ranks of the medical profession than from any other class of professional men because it strikes not only at the fundamental tenets of medicine as such but at bread and butter as well. The average physician is "vernünftig" anything which encroaches on his field.

"Cure" is always belated prophylaxis. If this statement is accepted, there will probably be no objection to the corollary that everything which will cure disease would have prevented it if applied at the proper time. Consequently the real problem consists in a sufficient understanding of the disease to forestall its activity. This leads to the very kernel of our subject.

That which faith will cure is the product of psychological processes which underlie that very same process of faith. Under medicinal methods the mode of attack is by opposition. Counteract, correct, cure are the slogans. Under methods of faith eliminate, ignore, entrust offer the escape. One is offensive, the other is defensive; one attacks, the other parries the thrust; one kills, the other runs

*Read before the Alumni Association, Med. Dept. University of Oregon, 1915.

for its life; one assumes responsibility, the other shifts the burden. Any condition that can be cured by faith has been caused by faith. *Vice versa*, any condition that has been caused by faith can be cured by faith—homeopathic psychology, if you please. This fact arises out of the very nature of psychology. Psychic life is a process and not a fixed quantum to be bandied about and dealt with in terms of quantity. If you ask what or where an idea is when it is not in consciousness, the only rational answer is that it is not at all; and, naturally, is nowhere. If by proper association a quiescent step in the process is again started, our consciousness undergoes a modification which we recognize as a former experience. Facts of which we are conscious for a moment immediately lapse into the subconscious unless they are sufficiently akin to the oncoming experience to be retained as an integral component of the existing process. Consequently, the past as psychic residuum can be modified only by a control of the elements which will go to make up the next conscious experience.

There is no psychic experience without its physical counterpart, and no physical disturbance without its psychic equivalent. Hence every experience which leaves its impress on psychic life, undergoes a continual modification, readjusting itself to the influx of new and varied physical stimuli. The reverse of this proposition must necessarily be true, viz., that every psychic state must find its complementary modification in the physical organism, leaving certain modifications of cells of more or less permanency according to the intensity of the modifying stimulus. If interaction of mind and body is admitted, the possibility of faith being a therapeutic agency must be admitted also. If, for example, psychic embarrassment is accepted as the causative agent in the production of a blush, the whole realm of psychotherapy is opened up and its limitations are marked by only two elements: (1) The possible intensity of the psychic emotion, and (2) the possible sensitiveness of the physical organism in which said emotion is to find its reflection. In fact, they run *pari passu*. By varying these two elements in relation one to the other, all degrees of physical and psychic disturbance can be obtained, from physical and psychic inertia to a most serious state of mental or physical shock. Where excessive emotional activity is correlated with extreme physical sensitiveness an unusual stimulus from either the physical or psychic may even wreck the combination, leaving on your hands a complete physical and mental wreck. No such calamity need be expected in the so-called phlegmatic individual. Here the governor is so regulated that an unexpected speeding of the engine is a physical and psychic impossibility. In such an individual there is comparatively smooth sailing. The powers of inhibition have such complete control of the situation that an outsider is unable to detect anything that would indicate that the inner flow of conscious life was not running in an even unvarying stream. Between two such individuals can be found all gradations and variations of physical and psychic reaction to external stimuli.

We know far more than we know that we know. Rarely a man is found who is able to retain the power of control over most of his experiences of the past. For the average man most experiences have a brief conscious existence and very soon sink into the subconscious, not to appear again until an appropriate association recalls the experience. Though dormant, as it were, their modification of

the conscious content is not to be ignored. Let the proper conditions be induced and the more prominent experiences will be reinstated for a moment, only to sink again beyond conscious control. By this process we accumulate a storehouse of latent experience which will emerge to full consciousness only under proper associations or conditions. Many of the so-called subconscious data continue their effect upon our everyday life even when we are entirely unaware of any past experience which would correspond to these subconscious states. Like the ticking of the clock, they so lose themselves in the general mass of stimuli which envelop us that we lose them in the general confusion, and only those of major interest attract attention. Let the clock suddenly stop, however, and we immediately become aware of the dropping out of an element of consciousness which was essential to our mental composure. It may even be some time before we are able to detect the underlying cause of the mental disturbance or uneasiness caused by the stopping of the clock, but we know something has happened to disturb our mental equilibrium. Start up the rhythmic ticking of the clock again and the mental machinery starts running smoothly as before; but, no sooner is the ticking of the clock reinstated as an element of our conscious content than it drops out of consciousness once more and we are unaware of its existence, though its absence demonstrated beyond a doubt that its presence was necessary to unimpaired activity of mind. It is said that in its wild state the rhinoceros is accompanied by a small bird which sits upon his back and warns him of approaching danger. He wanders about entirely unconscious of his little companion who lives upon the vermin to be gathered from his back, but let this little picket guardian be removed and the animal immediately becomes restless and uneasy, and his whole mental machinery becomes disordered, though he may be said to be unconscious of the bird so long as it is present. There is more truth than fiction in the story of the old woman who grew accustomed to the firing of the sunrise cannon and slept undisturbed through the noise only to find on removal of the camp that she was awakened by the cannon *not* going off at the usual time.

The same phenomenon is to be found by the race track. "Get his goat!" is an expression known to almost every street waif, and yet but few realize the full physiological and psychological significance which underlies the expression. The trick of stealing the race horse's goat was an effective means for defeating the racer the next day. In the presence of his usual companion, the goat, the nervous system of the horse was in a state of equilibrium due to the accustomed companionship of the goat, though it is safe to say that the latter formed no integral component of the conscious content of the horse as the hours passed. However, remove the goat and the equilibrium was destroyed. Restlessness and uneasiness robbed the racer of his night's rest, and the opening of the race next day found the victim of the trick unfit. In prize-ring circles the principle is well understood that if you can "get your opponent's goat" the fight is won.

In the same way many little insignificant experiences creep into or fall out of our daily conscious life, and they get their victim's goat. They disturb mental equilibrium and composure. The result is a neurasthenic, irritable, uneasy, and unfit for his usual responsibilities. Most neurasthenics are neurasthenics not because of some great shock, but be-

cause of the presence of some insignificant nagging stimulus of which they are not fully conscious. They know not whence their disturbing influences arise. Their real trouble lies within themselves, and they are entirely unconscious of its presence. Faith restores their goat. When the difficulty is unearthed and the victim is able to face his own subconscious experiences, the difficulty vanishes immediately. The unconscious becomes the conscious and is incorporated as an integral component of consciousness, subject to the general laws of inhibition which make rational mental life a possibility.

Many of us are narrow, bigoted and intolerant, because of teaching received in our boyhood. We have forgotten the teaching as such, we have passed on and left the conditions of those days behind us. We have forgotten those lessons as present conscious data, but they have not forgotten us, as it were. We do many things without knowing just why we do them. We fret and fume to-day because of some trivial, psychic shock in years gone by, and absolutely forgotten so far as recognizing in these past experiences any causal relation to our present disturbed mental state. Like sand in our bed, they disturb our rest but do not hurt us sufficiently to arouse us to a full conscious realization of their presence. A little psychotherapy under such conditions will help us to a consciousness of their presence and induce us to shake the sheet of them preparatory to a prolonged quiet rest.

The average neurasthenic cannot tell what is the matter with him. He does not know. He has no means of finding out, and yet in the majority of cases the trouble lies within himself. Certain elements in the subconscious have an effect upon him to such an extent that they undermine his inhibitive powers and destroy mental equilibrium. Any element having sufficient influence to effect the individual can usually be brought into full consciousness; if the proper methods are used, and in a large percentage of cases this is all that need be done to remove their baleful influence. The main error made in the treatment of such conditions lies in assuming that all individuals are built over a common mould and that the treatment applied will have like effect upon all individuals treated. He who reaps any benefit from faith as a means of cure is unfortunate in having the psychological characteristics which made the condition possible for which the curative process is to be invoked. Many people are sick because they are unable to inhibit or ignore injurious subconscious influences. Others are sick because they are unable to allow the subconscious processes to work to the betterment of their condition, unhampered and unhindered by fear and anxieties of full conscious life. In the great majority of cases faith is but psychological relaxation and in this condition the lower physiological processes are undisturbed and consequently do their work perfectly with a resulting normal health. Various sects express this psychological principle in different ways. The religious enthusiast—including the Christian Scientist—does the best he can and lets the Lord take care of the rest. Those who object to pinning their faith on the Lord do the best they can and let the rest "go to the devil." In either case the individual lays his plans, does the best he can, and under proper relaxation the subconscious does the rest. They are all expressions of faith in the consistent undercurrent of reality which will bring things around to a proper pass if one will only give it a chance. It is all a matter of mental adjustment.

Nothing will illustrate this principle better than the phenomenon of somnambulism. When the lower centers are allowed free play the somnambulist will pass through all sorts of dangerous situations and return to bed entirely unaware of his perambulations, the danger he has encountered, and the risks he has run. Intercept him in the midst of his dangerous feats, and disaster is the sure result. Why? The lower centers, if left alone, perform their functions without any conception of relation, and the result is automatism. Let the higher centers get in control, and the relation of things so disturbs the nervous equilibrium that nothing works right. Fear disorganizes the automatic mechanism. In full conscious life the man who never "loses his head" is the man that wins the day in a complicated situation. Such a man simply inhibits or ignores disturbing influences and forges ahead to the attainment of his one end in view. He has lost himself in the thing he is doing and the thing does itself. What is more, it does it naturally and without confusion. Give the conscious a job, and it may forget the job in the contemplation of self. Give the subconscious a job, and that job is completed in spite of adverse circumstances. Faith consists in trusting the job to some one else than yourself, and he who does not realize the powers within himself creates those powers outside himself. Confidence in such a power simply renders quiescent the disturbing influences which prevent the natural working out of the desired end.

All conditions in which mental attitude controls the physical processes can be cured absolutely if the normal mechanism of physical and psychic life can be reinstated. The cure has consisted in the removal of the fixed idea which has control of the situation. This fact is only too manifest in such demonstrations of the efficacy of faith as can be found in abundance in the history of the baths of Lourdes and shrines of similar character. Paralysis disappears like magic because of the faith engendered by the halo of mystery; and cures are accomplished beyond a doubt. But what is the nature of the paralysis and the other conditions that are cured? Usually the condition is the result of a fixed idea, and naturally when the fixed idea is removed the condition disappears. Once this is accomplished and the inhibiting, fixed idea is removed, the physical organism, previously held in abeyance, resumes its normal function. Frequently the patient's own self occupies his attention so fully that he sees nothing else. If he can be taught to ignore and forget himself, the cure is accomplished. He is enabled to forget himself and trust in an external agency by the atmosphere in which he is thrown.

History is replete with the wonders performed at the various shrines. Merely to laugh at all such demonstrations reveals an inexcusable ignorance and bigotry. The thing to do is to search for both the condition and the cure. These principles have nothing to do with religion as such. Therapy and religion have been closely associated because of the fact mentioned above, that when a man does not realize or loses control of the powers he has within himself there is always an appeal to an external source of help. This principle is to be found in its incipency in the fetich worshiper who sets up his fetich, prays to it, and then destroys it if his petitions are not granted. We need not go to past ages to find the same principle. Analysis of prayers which emanate from pew and pulpit reveals disappointment and at times even irritation on the part of the suppliant in the face of thwarted petitions,

even though the suppliant may close his appeal with "Thy will not mine be done." Through the feeling of helplessness in the face of the multitude of attacking agencies which beset us it is perfectly natural that the appeal for help should be to some power higher than ourselves. Religion furnishes this higher power, whatever may be our views or belief regarding the same, and hence we find religion and therapeutics closely associated. As our knowledge of natural forces has increased our appeal to supernatural agencies has decreased. We have learned that God helps him most who helps himself best.

This brings us to another phase of our subject, viz., to the extent to which faith-cure as an external agency is efficient in a given individual, to that extent did he fail to avail himself of the principles underlying so-called faith-cure as a prophylactic measure. He who is able to benefit by faith-cure could have prevented the condition for which faith was invoked if he had only understood himself. In other words, he whom faith will cure will find within himself the means not only of causing but of removing the condition against which faith is invoked. The real benefit of a faith-cure is in getting hold of one's self. The very essence of psychotherapy consists in getting the patient in position to avail himself of all the powers within himself. At times this end is best reached by dependence upon external powers or influences. But even by this method the gain obtained is by relaxation and submission. Thus the various metabolic processes are given their normal functions, mental and physical relaxation is obtained, and health is the result. To be sure, he who is ignorant of the real method of cure and the psychological principle underlying the same, attributes the cure to the external power in which he puts his faith, whereas the real cure consisted in allowing his own normal functions to have their normal play, undisturbed by baleful influences. Without the mental relaxation essential to a cure, the various functions of the body have been kept in a continual state of confusion, militating against one another, and naturally the result is a disordered physical organism.

The phenomena evoked in a good hypnotic subject illustrate beautifully the possibilities of positive suggestion upon a sensitive subject. Under hypnosis the subconscious becomes accessible, and where the subconscious can be controlled the power of suggestion is very strong. Any suggestion becomes real and is acted upon. At times these subconscious states become sufficiently intense to occupy the field fully to the exclusion of conscious data, and the result is an entirely dissociated personality. This process may and does occur in all degrees of intensity from mere absent-mindedness to a complete change of personality.

The aim of psychotherapy is to manipulate the psychic states of the individual in such manner as to allow the psychic process to follow normal channels. This is the very essence of faith-cure. Just this week there came to the office the daughter of an old lady whom, as the daughter says, the doctors had all given up as incurable. None of them seemed to know what was the matter with her. One gave one diagnosis, and another, another diagnosis. Finally the patient deserted the medical profession, and called in a divine healer. By the time the third treatment was administered the old lady could feel electric currents surging through her body, and to-day she is as well as ever. Did any advertisement for a patent medicine ever have a clearer ring as to

its efficiency as a cure-all than this tribute to the efficiency of divine healing? What healed the woman? It is folly to say that no change in her has taken place. It is equally foolish to attribute the cure to the treatment as such. In fact, there was no treatment, as physicians interpret that term. The divine healer knew less of what was the matter with her than the physicians themselves. Out of his blatant quackery emanated nothing but crassest inconsistency. His partnership with the divine smelled more of hell than of heaven. His self-confidence was exceeded only by his ignorance. Yet he succeeded when the medical profession failed. Why? Because he tapped the subconscious and the subconscious is more credulous than either he or his patient. He pressed the button, and the subconscious did the rest. Quacks often perform cures that baffle staid science in its adherence to physical dogmata. He in his ignorance understood neither the condition of the woman nor the cure he had accomplished. Doubtless he considered himself the instrument of God in the dispensation of health. His very claim as a divine healer leagues him with the mysterious and the supernatural. His own ignorance grows fat upon the ignorance of the public. His self-confident quackery finds its correlate in the credulity of a superstitious public, and back of superstition lies ignorance, mainly ignorance of one's self. The patient in her helplessness did all in her power as a conscious individual to regain her health. She availed herself of every means known to her in an attempt to get well. In her extremity she gave up and surrendered herself to the healing-powers of an external agency over which she had no control, and to which she submitted herself completely. It cured her. What is this "It"? Call it faith, if you choose; but it is evidently submission to something other than the conscious content of the individual as that individual has known herself for the past years. That complete surrender of self to an external agency robbed her of disturbing influences and allowed normal processes to establish a normal health.

It is needless to multiply instances illustrating the principle. Every physician has encountered them to his own embarrassment and humiliation. To say that the various cults do not perform cures, and as real cures as redound to the glory of the medical profession, is but to shut our eyes to the truth. To attach the principle to religion and make pilgrimages to shrines simply ignores the psychological principle involved in the cure and which finds exemplification in every individual. He who carries from a shrine cure for his ailment carried to that shrine both the cause of his ailment and the means of cure for the same. In other words, shrines and their deities will cure nothing that mental attitude cannot adjust. "Ah, there's the rub!" Then how is the mental attitude to be obtained? If the shrine is necessary, go to it. Many, however, get the cure in the seclusion of their own study, facing themselves without shrine or deity. Others need a helping hand, for they themselves do not know what ails them. Here comes in the mission of psychoanalysis. By its help the subconscious can be investigated and frequently in the subconscious is to be found the whole cause of a wrecked life, while the individual is entirely unaware of the same. In fact, the subconscious offers an extremely prolific source of therapeutics, and when the medical profession uses hysteria as a diagnostic dumping ground it is not surprising that the sects, isms, and cults grow fat upon the ignorance and credulity of the public, to the dis-

comfiture and embarrassment of the medical profession. Psychic life is more than a mere evanescent effervescence from brain tissue, and by an analysis of the psychic life of the individual many unsuspected causes of disease can be unearthed. These causes and conditions are amenable to treatment, but they cannot be reached by the knife and pharmacopeia.

THE AMERICAN METHOD OF CATARACT EXTRACTION.

By JUAN SANTOS-FERNANDEZ, M.D.,

HAVANA, CUBA.

WE intend to be brief in this communication and shall develop our opinion without falling into tiresome details, but missing nothing that would be pertinent to this paper, derived either from our own experience or from the observation of the work of the best ophthalmic surgeons of Europe and the United States. The latter have created a distinct method of their own which could be fairly called the American method of cataract extraction.

When we began to study the diseases of the eyes, the primitive method of couching the cataract had been abandoned definitely, but there were some who were still afraid to resort to the method first described by Daviel in 1752, and seconded by Mery, Du Petit, Saint Ives, and others.¹ De Graefe's imagination thought to solve the difficulties that were attributed to the corneal flap extraction by means of his method of peripheral lineal extraction with iridectomy. In this way the corneal flap was greatly shortened because in the peripheral lineal extraction the sclera was also engaged and by subsequent iridectomy, the delivery of the lens was made easier. Before his premature death at Berlin in 1870, the illustrious master was able to see that his method, although it might pave the way for future work, would not supersede the classic method of Daviel in which a flap of half the cornea was dissected up. For thirty years after De Graefe's initiative, the most noted surgeons of the last half of the 19th century, among whom were Jacobson, Stellwag, Carrión, Panas, De Wecker, Galezowski, Critchet, Weber, Horner, Pagenstecher, and others whose names do honor to the history of Ophthalmology, described many procedures based upon the idea of Daviel and on the initiative of De Graefe, having in mind the intention of obviating the real or supposed dangers of the large flap of Daviel.

Those fears were lessened or partly extinguished by the almost simultaneous discoveries of the application of local anesthesia and of antiseptics based upon the work of Pasteur; and from now on the percentage of statistics was very favorable as concerned the loss of the eyes after the uncomplicated extraction of mature cataract.

Later on for a score of years ophthalmic surgeons made many efforts to avoid another obstacle that still persisted and which consisted in the dangers provoked by the increase in intraocular tension, caused by the cortical material of the cataract remaining in the eye, but not reaching the degree of glaucomatous tension. But as the cortical material, when swelling, reopened the borders of the corneal incision, even six or eight days after the most perfect operation of simple cataract extraction, not seldom this caused partial or total herniation of the iris. To avoid this has

been the special care of oculists in recent times; this may have been done by means of irrigation of the anterior chamber or in some other way.

One of the first precautions has been to operate only upon ripe cataracts without any cortical material, but even this does not always prevent the accident. The absence of cortical material is not enough to guarantee the absence of other complications or to render an operated eye immune from the dangers that arise from the increase in intraocular tension and from hernia of the iris.

Conservative surgeons especially believed that irrigation of the anterior chamber, thus clearing it of any cortical material, would be sufficient to remove the dangers that were feared, but others less timid had recourse to iridectomy because in consequence of the partial removal of the iris the dreaded increase in intraocular tension could not cause eventration or other complications.

Following again a conservative opinion, that of avoiding iridectomy, suture of the cornea,² without omitting the irrigation of the anterior chamber, was suggested, although there has been more or less opposition to the latter procedure.

This appeared to have solved the problem, especially when others substituted, as being more rational, the making of a conjunctival flap for corneal suture,³ a device that had been practised by Desmarres, but with another object in mind. The conjunctival flap holds together the borders of the corneal wound, the same as suture of the cornea, and equally avoids prolapse of the iris, being besides of easy practice as well as free from any complications. It has been tried more or less by numerous ophthalmologists, among whom are Landolt, Snellen, Morax, Czermat, Wecker, Fuchs, Axenfeld, Blanco, de Lapersonne, May, Weeks, Arnold Knapp, and others. It seemed as though the question could be limited either to the corneal suture or to the formation of a conjunctival flap, without excluding in both methods irrigation of the anterior chamber if necessary; but at this time one of the more ardent defenders of corneal suture, Dr. Valude of Quinze Vingts,⁴ Paris, associate of Chevalereau and Kalt, who had been practising it since 1894, declared himself vanquished and acclaimed the combined extraction method, being convinced, after having had experience in all, that it was the safest procedure.

We do not doubt this in the least, and we have seen it more than once in our own practice; but we have always regarded it as a non-conservative and complicated method, because iridectomy is harder to perform than the simple extraction, since in this latter operation the only instruments required are a lid elevator, a knife, and the fixation forceps. Even the assistant can be omitted, who is otherwise indispensable in the operation of iridectomy if we do not want to expose ourselves to the danger of a laceration of the iris when the patient is not obedient or is oversensitive.

The combined extraction method followed by irrigation of the anterior chamber was seen by us frequently in New York in 1909, when we accepted the courteous invitation which was tendered us by the American Academy of Ophthalmology and Oto-Laryngology, and we have alluded to this practice several times in our own papers.⁵ At this time we saw the combined extraction with conjunctival flap done by all the ophthalmic surgeons of New York, as if by common agreement,

and iridectomy was done only when the cataract was immature.

This unanimity in a large number of surgeons could have been due only to the fact that they have obeyed their own experience, anticipating themselves to what was later done in some parts of Europe; and it clearly shows by a forced psychological deduction that they felt the necessity of returning to the ideas of the two masters of the 18th and 19th centuries, Daviel and De Graefe. We believe, therefore, that we are justified, as we said before, to call the cataract operation, as it is practised in the United States, the American method of cataract extraction. In this operation we have never seen the escape of the vitreous because this is an accident that the American surgeons take great care to avoid. The combined extraction is slower and requires greater ability on the part of the surgeon. It also slightly affects the roundness of the pupil, that in some patients is almost unnoticed, but these objections are of small importance when we consider the certainty of the recovery of vision with the smallest possible risk of injuring the eye.

In order not to lengthen this paper unduly we shall mention only three cases that show very evidently the security afforded by iridectomy and the danger run when it is not practised.

CASE I.—The patient was an engineer who wanted the operation on his left eye done before maturity, in order to avoid the continued growth of his right cataract. Although we feared to operate because of the rapid development of the cataract, we nevertheless did operate, resorting to the combined extraction as a precaution. At the end of four days the wound was healed, but when eight days had passed he complained of not seeing. We could not explain this phenomenon, but with the ophthalmoscope we were able to discover a pyramid of cortical material on the posterior capsule. This was absorbed in course of time without the slightest inconvenience. This could not have occurred if iridectomy had not been done.

CASE II.—In this case we operated upon the left eye of a colleague whose right eye had also been operated upon before by us. This simple extraction was easily done, and for eight or ten days the patient was feeling well, but one morning he told us that he had suffered a short and severe pain during the night. We suspected what had happened: the pupil was slightly irregular, and not rounded and on the next day the iris was found to be prolapsing, and it took sixty days to combat it because we did not want to excise it, being afraid of infection.

CASE III.—This case clearly shows the advantages of the conjunctival flap. The patient was a lady not over 45, who had a simple extraction made without any difficulty. We dissected the upper conjunctival flap without being afraid of its size, for the larger the better. For four days after the operation the patient felt well, but the anterior chamber was filled with cortical material. We trusted in the flap and in the absence of any inflammation and let her go home on the fourth day, for she lived in another town. She came back in 30 or 40 days, when the cortical material was found to have disappeared, and later on she obtained perfect vision.

From what we have said we can gather the following: There is a unanimous tendency towards practising the combined extraction operation, and while this is generalized we can make the following conclusions:

1. Although cataract operation has reached a high degree of perfection it has slight inconveniences that often give rise to the fear of an unfavorable result following even the most skilful operation. The fear of complications, however, may be dismissed when to the combined extraction operation is added the formation of a conjunctival flap.

2. In any case of old senile cataract with no cortical material, simple extraction is enough if a conjunctival flap is also made.

3. Suture of the cornea in cataract extraction may be resorted to by those surgeons who are accustomed to it and in cases in which they consider it necessary.

THE MARANTIC STATE.*

By CRAWFORD R. GREEN, A.B., M.D.

TROY, N. Y.

THE term marasmus, to indicate a disease, has disappeared from modern medical nomenclature and no longer appears in good repute as a cause of death. Marasmus to denote a syndrome, however, may lay some claim to respectability, though its synonyms—infantile atrophy, infantile wasting, or the marantic state—are doubtless preferable. In the previous generation, marasmus, the disease, covered a multitude of diagnostic errors, and marasmus, the syndrome, is still confounded by a wealth of ignorance. What we do not now know about this condition will be pointed out clearly enough, no doubt, at some future time; for the present, it presents so much of mystery, that it quite suffices that we humbly confess to no small degree of ignorance regarding it.

The marantic state as an underlying cause of death doubtless plays more havoc than any available methods of investigation could possibly disclose. The underlying disturbance of metabolism which has caused a child to become atrophied and weakened is very often unrecognized as primarily referable to the digestive tract. Erroneous pathological reasons are assigned for the wasting; perhaps the bronchial cough, which almost every marantic child develops, is seized upon to make a possible (or passable) diagnosis of tuberculosis, or perhaps the conclusion is jumped at that the wasting is due to unproved syphilis or congenital heart defect. The child may die of pneumonia, or measles, or whooping cough with no appreciation on the part of its attendants of the fact that the child would not have died had it not been robbed of its natural resistance and weakened by inadequate nutrition—inadequate becomes unassimilable.

We need not here enter into the attempts that have been made to explain this wasting. It is of interest to note, however, that there are those who would have us believe that it is due in all cases to high fat feeding—high fat being a relative term, for very low fat may be very high in a given case. It would be well if this were so, for many of the marantic babies we meet have wasted as a result of protracted fat indigestion that one would readily

*Read before the Rensselaer County Medical Society at Troy, N. Y., February 8, 1916.

believe it, if it could be proved to be the case. But what of the marantic babies one sees so frequently in dispensary practice that have had no food but condensed milk—that is, no fat at all? These condensed-milk fed babies form a goodly percentage of all the marantic cases, but their presence in the records of a given practitioner is determined largely by the social condition of the cases that he sees. The condensed-milk fed baby, however, though he receives no fat, does receive an excess of sugar. Experience and reason would, therefore, lead to the conclusion that the excess of an ingredient, and not a particular ingredient, in the baby's dietary is the underlying cause of the marantic state. Nature struggles along valiantly trying to assimilate an excess of some nutritional element. Sometimes she succeeds, for far more babies get along with excessively high fat or sugar than do not. Sometimes she fails, an explosion occurs, and unless the condition is at once recognized and the cause removed, we soon have the typical picture of wasting and severe digestive disorders of both stomach and bowels, and at length the patient belongs to that class that has been so aptly designated "mournful looking little old men and women."

What has happened in these cases is simply that the power of the infant to assimilate a certain element has been so greatly overtaxed that it has reached a point where it cannot assimilate the ingredient at all, unless given in minute quantity. To the unknowing the treatment seems superlatively irrational. The patient is emaciated to the last degree, its body is but skin and bones, and the casual observer would naturally conclude that above all else it needs fat. Fat indeed it sorely needs, but animal fat unfortunately it cannot take, and, so long as it is given, the child will assimilate no food. There can be no sadder picture than that of the young mother trying this food, that food, and even some other food, doing in turn all that all the neighbors are ever ready to advise, and yet consigning her child to the grave for the want of a little—just a very little—knowledge that none of her advisers possess! The cemeteries contain hosts of these babies that need never to have died in infancy at all.

The salvation of the marantic child depends upon feeding it no fat. This is true of the condensed milk marantic as well as the high fat marantic, for the marantic condition itself seems to preclude fat assimilation, whatever the primary cause of the wasting may be. Skimmed milk is the sheet anchor of treatment. It makes no difference what other ideas we may cherish as to what to dilute it with, or how many fads and fancies about special foods we may harbor, every result we accomplish will be derived from feeding food devoid of animal fat. No patent food, nor malt soup, nor malted milk, nor whey, nor any other preparation can have the slightest value unless given without cream.

There are but two constant rules for feeding marantic babies. They are: (1) remove all or nearly all the cream, and (2) keep the sugar low. The feeding of marantic babies will vary with every case. One may require plain water with milk and another may need barley gruel; one may need malt sugar and another milk sugar; one may need a laxative and another an astringent; one may require but little food at a feeding and the other much—but all of them need *freedom from fat*.

If skimmed milk is to be used, the baby should

first be put upon a formula containing less skimmed milk than normally it would take of whole milk or top milk at its weight. The skimmed milk should then be slowly increased until the normal amount is being received for the given weight. Then, after some days, slowly, cautiously, watchfully work in a little cream—ever so little at first—perhaps skimming off all the cream from the quart bottle except half an ounce. Then in a day or two work in another half ounce and keep working it in, a little at a time, until the tolerance for it is again acquired and the baby can digest whole milk.

Not infrequently so much digestive disturbance is present that skimmed milk cannot be digested at first, no matter how we may dilute or modify it. In these cases, whey is often useful. If well borne, it may be given plain until improvement begins and then a little cream may be carefully introduced in the whey. One ounce of cream to every 20 ounces of milk increases the fat in the food 1 per cent. After a few weeks of this feeding the digestive conditions have usually so improved and the tolerance for fat so increased that we can change to some appropriate modification of milk. Paradoxically, condensed milk may be of temporary use. In marantic cases due to high fat feeding, condensed milk will succeed when everything, except the wet nurse, will fail. A marantic baby of three months with subacute diarrhea lost steadily on skimmed milk, whey, *eisweiss milch*, barley, and albumin; given condensed milk (one teaspoonful to four ounces of water at first) it gained $\frac{1}{2}$ lb. the first week, and kept on gaining steadily.

The successful conduct of these cases demands fresh air and sunshine abundantly. Fear, the handmaiden of ignorance, consigns many of them to a life indoors. These are the babies that are most apt to have pneumonia or to become tuberculous. The baby should be outdoors continually during all the sunny part of the day. Most marantic babies get rubbed with oil—the oil tradition is well cherished by the laity. We now know that oil is not and cannot be absorbed through the skin. The practice, nevertheless, is not devoid of merit, for the massage itself is of some value by stimulating the circulation. Olive oil internally—a teaspoonful three times daily is rational and useful. The vegetable fat, which the child can assimilate, helps to a degree to compensate for the lack of animal fat, which it cannot assimilate. Lately, a method of feeding has been devised which utilizes this principle. I refer to homogenized olive oil and fat-free milk, which is a combination of olive oil and milk in which the oil globules are so treated that the oil makes a homogeneous mixture with the milk. Theoretically this would seem to be an ideal food for marantic babies and practically it has given good service in a limited number of cases upon which it has been tried. Unfortunately, the production of this food requires an elaborate apparatus which is as yet within the reach of comparatively few.

25 SECOND STREET.

Protective Power of Clothing Against Cold and Damp.—Professor Terni thinks that cotton composed of twisted fibers, and having a large content of a much more stable fatty material than wool, can be made up with a very small loss of this fat. Thus can be obtained a material, economical, equal to wool in protection against cold and damp, and with a marked reduction in weight—a fact of importance to those who work while on the move.—*The Lancet*.

MEDICAL RECORD.

New York, March 18, 1916.

THE ADVERTISING OF DRUG ADDICTIONS.

THE fact that the application of the provisions of the Harrison Law (which has had its critics and its defenders, and of whose pragmatic value we can probably form no just estimate as yet) unearthed, suddenly as it were, at least a million drug habitués, seems to have been a matter of surprise to many. Of all the speculations which are induced by this disclosure not the least interesting is the question how this vast throng acquired the habit. We are of course familiar with the story, so frequently and carelessly given, reflecting on the family physician. The story of an acute illness, with its attendant pain or insomnia, the exhibition of morphine, the exaltation experienced by the patient, his subsequent convalescence and indulgence in the drug to tide him along until complete recovery, and his discovery coincident with, or it may be even before, the latter event that he cannot now do without the drug.

Now this is all very well and probably accounts for a certain number of cases, but it undoubtedly gives rise to many entirely too sweeping condemnations of the profession. Medical men on their part have published their broadsides against the patent medicine industry, the nostrum with a small percentage of opium being especially attacked. According to them the neurasthenic, the hypochondriac, or the self-pamperer reads the circular, studies the label and prescribes for himself Dr. X's Xellent Xample. He gets therefrom the classical symptoms of narcotism, and the feeling of well-being and self-satisfaction which follows the ingestion of the drug precludes any but pleasant feelings. The dose necessarily increases with the tolerance and sooner or later the patient, for such he is in sober reality now, becomes aware that he cannot live without the drug. Whether he continues to get it in the form of the original mixture or turns to some more direct way is a matter of little moment.

This latter method of acquiring an addiction is held to be of prime importance by some. We have been told by officials in the Internal Revenue Office who deal constantly with addicts that it is estimated that 85 per cent. acquire their habit in this way. Probably this, too, is an exaggeration. There has been too little stress laid upon that aspect of human psychology which is responsible

for the desire for something above and beyond the ordinary emotional experiences, the "will-to-power" of Nietzsche even if that power be only a belief-compelling phantasy. Poe has said, "Induction, *a posteriori*, would have brought phenology to admit, as an innate and primitive principle of human action, a paradoxical something, which we may call *perverse*ness, for want of a more characteristic term. In the sense I intend, it is, in fact, a *mobile* without motive, a motive without *motiv*irt. Through its promptings we act without comprehensible object; or, if this shall be understood as a contradiction in terms, we may so far modify the proposition as to say, that through its promptings we act, for the reason that we should *not*. In theory, no reason can be more unreasonable; but, in fact, there is none more strong. With certain minds, under certain conditions, it becomes absolutely irresistible. I am not more certain that I breathe, than that the assurance of the wrong or error of any action is often the one unconquerable *force* which impels us, and alone impels us to its prosecution."

Admitting that this tendency is present in all of us, and a moment's introspection will forbid that we deny it, why should the vast lay public become so intimately acquainted with these drugs? From the classical "Confessions of an English Opium-Eater" of De Quincey to "Shadows of Flames" by Amelie de Rives we have had volumes of printed material dealing with the drug. At the time the Harrison Law was projected the lay press was filled with special articles on the subject. Following the enforcement of the law highly colored stories appeared, dwelling upon the intense sufferings and the crimes engendered by the sudden deprivation of the drug.

It is a matter of common knowledge that slang allusions to drug addictions pass for humor in many circles, not excluding the highest. It is small wonder then, when he who runs may read full information about morphine and other narcotics, that many have impulses to try them. It is, of course, begging the question to say that these public accounts of opiumism deal almost invariably, in part at least, with the suffering attendant upon drug addiction. This makes but little impression upon such natures as are impelled by an ungovernable curiosity, uncurbed by any very well-defined ethical restrictions, the sort of attitude which is rather well summed up in a cant phrase of the day, "I'll try anything once." Was there ever an addict who believed that the drug could become his master until it was proved to him by signs which he could no longer ignore?

By way of prevention, then, medical men should refrain from disseminating the knowledge of habit-forming drugs except, of course, as they are called upon to do so in the treatment of addictions, should refrain from alluding to them in facetious vein, and should influence where they can, the lay press to do likewise. Others who may help in this direction are those who necessarily, in the course of their daily occupation, obtain a varying amount of this knowledge—the pharmacist, the nurse, the veterinary surgeon, the manufacturing chemist, and the lawyer.

A CLINICAL STUDY OF CHRONIC DIARRHEA.

CHRONIC diarrhea is a relatively infrequent complaint in those places in which amebic and bacillary dysentery are absent, although, as it may arise from other causes, it is present to a greater or lesser extent almost everywhere. In the *American Journal of the Medical Sciences*, February, 1916. Dr. Dudley Roberts has a paper dealing with chronic diarrhea from the clinical standpoint. He gives the history of twenty-two cases of the condition and states that in studying these cases he has been impressed with the number of times that concomitant conditions could be held accountable for the looseness of the bowels. In eight cases examination disclosed a definite catarrhal colitis. In two cases examination showed an amebic ulcerative dysentery, and the diarrhea was cured by ipecac therapy. In three cases there was colitis, and many organisms of the flagellate group were found in the fresh dejecta and gastric contents. Local treatment of the stomach and colon by irrigation resulted in a temporary cessation of the diarrhea and the temporary disappearance of the flagellates, but in no permanent relief. In two cases there was seen achylia gastrica in elderly men with atrophic colitis. In four cases there were periodic outbreaks of acute serous colitis characterized by the passage of enormous quantities of practically odorless fluid rich in serum albumin. In two cases there was a definite pulmonary tuberculosis and a good deal of suspicion, although no positive proof of tuberculous enteritis.

From these observations Roberts is led to the opinion that achylia renders the individual more liable to chemical, mechanical, and microbic injury, which gives rise either to irritation of the colon with undue stimulation of peristalsis or to acute attacks of inflammation or to chronic changes in the mucosa. Roberts' summary is as follows: (1) Chronic diarrhea is a relatively infrequent affection. It may complicate any morbid condition, but in the study of this series of cases the attempt has been made to determine the factors responsible for the disturbance of bowel function. (2) Achylia gastrica occurs in about one-third of all cases, but is to be regarded as a predisposing cause of irritation and inflammation of the colon. The most satisfactory results in diarrhea associated with achylia were obtained by the treatment of colonic stasis by diet and of the colitis by appropriate measures. (3) Colitis is not necessarily accompanied by chronic diarrhea, but, particularly in the nervous, seems to give rise to irritability of the colon, which causes frequent evacuations. (4) Colonic stasis may give rise to chronic diarrhea, and dietetic measures which increase peristaltic activity quiet the apparently already overstimulated bowels. Stasis is probably an important predisposing factor in colitis, for the permanent relief of the colitis depends largely on overcoming stasis. (5) Emotional excitability may at times be a factor in causing diarrhea, but nervous states are rarely to be regarded as the sole cause of chronic looseness of the bowels. (6) Hyperthyroidism frequently gives rise to a chronic diarrhea of moderate severity. It

differs in this particular from the severe diarrhea, attended with emaciation and prostration, which accompanies destruction of the adrenal gland. It seems quite probable that the latter condition is more common than has been recognized, and is not entirely dependent on the destruction of the gland substance. (7) Success in the treatment of chronic diarrhea is peculiarly dependent upon the exhaustive study of the case by all diagnostic resources, particularly as a combination of factors is not infrequently responsible for the normal activity of the bowel.

THE THERAPY OF IMMORTALITY.

FEAR of death is perforce the most universal of fears. Hall has selected it from the multitude of phobias which harass mankind for a most interesting discussion of the treatment of "Thanatophobia and Immortality" (*American Journal of Psychology*, October, 1915). The dominant note sounded throughout this discussion is one of supreme pragmatic significance. It fixes attention upon the therapeutic reaction of mankind whereby the race has turned to account this otherwise overwhelming fear and obtained from it an incentive and momentum toward the fullest development of life.

The fear of death is the great negative of the will to live. As such Hall compares its place in individual and racial history with the psychology of reproduction, the opposite pole. Both are extreme experiences and thus both are repressed, from both attention is diverted to accessories, to anything that will prevent or postpone the direct envisagement. Again a concentrated interest in either is first manifested at puberty when life moves toward flood tide. It is then that death manifests itself as a reality, even though the very fulness of life at this time urges the latter's claims more strongly. Advance in age and experience but confirms the fact that death cannot be denied. How then shall the individual confront this, how has the race met it in the past?

The immortality of the race is older than death. Therefore its demand cannot be denied. It has various modes of expression which in turn enhance and elaborate the genetic instinct. There are four chief forms of immortality by which man has sought to satisfy himself; these Hall has named the nominal, influential, plasmal, and orthodox. The first would perpetuate one's name, craves that remembrance at least shall survive death; the second seeks to live on in some service to posterity though the individual name may be forgotten; plasmal immortality is satisfied in offspring, but has its roots genetically so deep that we are but beginning to grasp its significance in all that immortality means through its source or its irradiations and sublimations; orthodox immortality has long directed attention to another life where death may be denied and the will to live may find its most exorbitant phantasies actualized.

Each one of these, selfishly individual or racial in aim, has served a developmental purpose. Even the most self-seeking form has freed man from that

morbid fear that would have blighted all effort and checked all advance. It has transformed the aspect of death or has centered attention upon and directed effort to achievements that should outlive death. In any form it has given a buoyancy and intensity which have been immeasurable progressive forces. Hall gives other groups of theories of immortality which occupy men's thought. All, however, are expressions in one form and another of the fundamental will to live, of the desire for assurance against its opposite extreme. Individual immortality gives this assurance to some, others find it in absorption into the cosmic whole. Nevertheless the therapies of past beliefs have brought us to a fuller and more intense concentration upon this life, and as a result we are building better for the future of the race, while as we slowly overcome the fear of death we are enabled to turn to it with a truer scientific interest which will reveal important facts which fear and loathing have hitherto concealed.

THE FUNCTION OF MILK IN THE SCHEME OF EVOLUTION.

IMMEDIATELY after birth, and before the processes of digestion are established, if soluble proteins are introduced into the stomach of an infant, a certain proportion will be absorbed; if, however, these proteins are foreign, for instance those contained in cow's milk, they will excite biochemical reactions, and lead to the production of specific precipitins in the blood, and therefore they will not subserve the functions of ordinary nutrition.

Dr. Henry D. Chapin writes in the *Scientific Monthly*, January, 1916, on the function of milk in the scheme of evolution and notes that while the carbohydrates and fats in their composition and reaction to the digestive secretions are a good deal alike in different milks, the proteins are essentially different. It is further to be noted that coagulation of the proteins of milk takes place in different degrees in the different species. Thus we are led to two queries: (1) What is Nature's object in presenting a fluid that always coagulates in the stomach that receives it, and (2) why do the milks of different species coagulate in different ways? An answer will be found in studying the relation between the milk and the particular digestive tract that is destined to receive it. While a certain portion of the protein of all milks coagulates on coming into contact with rennin or rennin and acid, the manner and extent of the coagulation will stand in a direct relation to the proper evolution of the digestive tract of the animal.

The milk of herbivorous animals, whose digestion is principally gastric, forms solid curds that cannot easily leave the stomach; on the other hand, the milk of those herbivorous animals whose digestion is principally intestinal, forms gelatinous curds which easily leave the stomach and pass into the intestine. Woman's milk, which is intended for a digestive system in which gastric digestion is more than that of the horse and ass, but not so great as the cow or goat, curds in flakes that stand between the other two types of milk. Hence, it is a law that coagulation of the proteins of milk always

takes place in such a way as most readily to adapt the digestive tract for its future work, as this function needs special preparation. It will be then seen that while a certain amount of protein is present in the milk of all animals and is necessary for tissue building and growth, this protein must not only be coagulable, but must curd in a certain specific way in each species of animal for the proper evolution of their digestive tracts.

The fact then must be emphasized that milk through its protein has a developmental as well as a nutritive function to perform in developing and preparing the digestive tract so that it can digest and assimilate food that must nourish the animal in later life. The directly practical point to be deduced from the study is of course the importance of every human mother suckling her own offspring.

EXPERIMENTAL PRODUCTION OF PURPURA HÆMORRHAGICA.

THE close relationship between a diminution in the number of blood platelets and purpura hæmorrhagica has been well known for many years. It has also been shown that an antiplatelet serum can be produced by the injection of alien platelets into an animal and that such serum contains highly specific antibodies. Antiplatelet serum agglutinates platelets both *in vivo* and *in vitro* and eventually has a lytic effect upon them. Lee and Robertson (*Jour. Med. Research*, 1916, xxxiii, 323) have verified the above results and extended their application. They showed that the agglutination and lysis of the platelets require the presence of complement and that complement is actually used up by the reaction. When whole blood was used the mixture clotted in the usual time but the clot did not retract. Their antiplatelet serum was produced by the inoculation of guinea-pig platelets into rabbits. When guinea-pigs were treated with this serum their blood showed an immediate and marked diminution in the number of blood platelets, which was but temporary since the number was again normal in about three days. Coincident with the reduction of platelets there was produced in the pigs "a condition typical in practically every way of the acute form of purpura hæmorrhagica seen in man." There were numerous and profuse hemorrhages, a greatly delayed bleeding time, and a normal coagulation time, but no retraction of the clot. The authors were unable to gain any information as to the manner in which these hemorrhages were produced by histological examination of the hemorrhagic areas. This is very valuable information and the work, if successfully carried on, may lead to the discovery of some method of therapy which will give better results than any we are able to apply at the present time. Transfusion is only too often without favorable effect and the idea of an anti-antiplatelet serum is a fascinating one.

TYPHOID IMMUNIZATION AND LATENT LUES.

THAT the local and general reactions due to injections of sera sometimes light up latent maladies is not surprising, and, in fact, the presence of damaged organs usually offers a contraindication to attempts at immunization. Among young soldiers, however, there should be no latent disease, unless it be syphilis, and the Wassermann reaction should be used in any suspicious case before accepting the

recruit. Nevertheless, latent cases must now and then pass the examiner, and it is only strange that the awakening of syphilis has not been noticed more frequently after immunisations against typhoid fever. Such an accident is of interest in several ways. The patient is made aware of the existence of his disease, which should readily yield to a salvarsan treatment. On the other hand, he may feel that he has a case for damages through some after-development. In the *Münchener medizinische Wochenschrift* for December 21, Burdach describes the case of a soldier, aged 40, who was immunized against typhoid fever. The local reaction, instead of subsiding, began slowly to extend itself, and no treatment was of avail. Syphilis was vigorously denied, but the Wassermann reaction was strongly positive. When the man's chest was examined the skin was found intact, but a number of subcutaneous nodules were present in the vicinity of the immunizing injections. Vigorous treatment caused a rapid subsidence of the gummata. The disease had probably been contracted some twenty years before.

News of the Week.

City Death Rate.—During the week ending March 4 the total deaths reported in New York City amounted to 1,603, giving a death rate of 14.97, as compared with 1,628 deaths and a rate of 15.20 for the previous week, and 1,548 deaths and a rate of 14.81 for the corresponding week of 1915. There were thus 55 more deaths recorded during the week than during the same week of last year, but all but seventeen were accounted for by the increase of population. The deaths from heart disease, Bright's disease, influenza, bronchitis, and pneumonia were all increased in number as compared to last year, but less numerous than during the preceding week. The death rate for the first ten weeks of 1916 is 15.94 per 1,000 of population, as compared with 14.78 for the corresponding period of 1915.

Decrease in Tuberculosis Death Rate.—The National Association for the Study and Prevention of Tuberculosis recently called attention to the figures covering tuberculosis contained in the United States Census Report for 1914, which show that the death rate from the disease has decreased from 200.7 per 100,000 in 1904, to 146.8 per 100,000 in 1914, a drop, that is, of more than 25 per cent. in ten years. Notwithstanding this decrease, however, tuberculosis caused about 10.5 per cent. of all the deaths in the registration area. As explaining the improvement in conditions, it is stated that in 1905, when the anti-tuberculosis campaign was definitely started, there were in the United States only 39 anti-tuberculosis associations, 115 sanatoria and hospitals, 20 special clinics, and no open-air schools, whereas, at the close of 1915, there were more than 1,500 associations and over 100,000 persons actively interested in combating the disease, 660 sanatoria and hospitals, 450 dispensaries, and 800 open-air schools.

Measles in New Jersey.—An epidemic of measles among the school children of Orange and of Montclair, N. J., has been reported, due, it is said, to wrong diagnoses and inefficient quarantine at the outbreak of the disease. It is stated, also, that many of the children who were sent out from day schools because suffering from the disease were permitted by their parents to attend the

sessions of the Sunday schools. The health departments have consequently issued orders that children excluded from school must not be permitted to leave their homes until the quarantine has been lifted by an official of the department.

Health Department Celebrates.—The fiftieth birthday of the Department of Health of the City of New York was fittingly celebrated by a dinner at the Plaza Hotel on March 9, by 250 members of the department and their guests, among them Commissioner Emerson, Mayor Mitchel, Dr. Stephen Smith, who was Health Commissioner in 1866, former Commissioners Dr. J. B. Cosby, E. J. Lederle, Thomas Darlington, and S. S. Goldwater, Dr. Peter H. Bryce, Provincial Health Officer, Canada; Dr. Abraham Jacobi, Dr. William T. Jenkins, Prof. William H. Welch, Dr. Alvah H. Doty, State Commissioner of Health Hermann M. Biggs, and Assistant Surgeon General John W. Trask of the United States Public Health Service.

The Radium Institute of New York has established a weekly clinic at 205 West Seventieth Street and extends a general invitation to medical men to be present any Saturday afternoon. These clinics will be of service to all those interested in the treatment of malignant and benign growths with radium or such adjunct measures as seem indicated. Opportunity will be given to follow up the histories of all cases, and advice will be given relating to any problem of radiumtherapy that may arise. The institution is provided with adequate amounts of radium element. Screenage and dosage are being checked up by instruments of remarkable precision, and much of the results obtained will be presented in the first semiannual report in May. In addition to the use of radium the institute is provided with apparatus for diathermy and x-ray treatments. While it is not true that the institution is based solely on philanthropy, it is nevertheless the purpose of the dispensary or out-door department to give aid to as many as possible at a small fee that will support maintenance. As soon as the work can be fully systematized the entire radium will be kept busy for the full twenty-four hours a day. Certain hours are to be set aside for charity patients, and in giving aid to the class of deserving poor afflicted with malignant growths who are now without hope, the sanatorium expects to relieve much suffering. No case will be turned away, for palliative treatment at least can be offered.

Psychopathic Dispensary.—The attention of physicians of Manhattan and the Bronx is called to the free dispensary for the treatment of psychopathic conditions, especially the milder forms, which is maintained by the Cornell University Medical College in conjunction with the Mental Hygiene Committee of the State Charities Aid Association. The work of the dispensary is done chiefly by the staff of the Psychiatric Institute of the New York State Hospitals and by two social workers on the staff of the State Charities Aid Association, who assist the examining physicians at the clinic and when desirable visit the patients in their homes. The cooperation of physicians throughout the city is most earnestly desired in this campaign for the prevention of insanity.

College Increases Requirements.—At a meeting of the Trustees of Columbia University, New York, held on March 6, in addition to the decision to admit women to the College of Physicians and Surgeons, the medical department of the University, as soon as suitable provision could be made, as was

noted in this column last week, the Trustees also voted to increase the entrance requirement to the college to at least two years of college work aggregating seventy-two points, as rated at present in Columbia College for the candidates for the combined course, the requirements to include physics, biology, organic and inorganic chemistry, English, and French or German. It was also decided that, contingent upon financial ability and suitable hospital arrangements, the curriculum of the college be extended from four to five years and include for each student one entire year of practical work in a hospital before the granting of the degree of doctor of medicine.

"Baby Week."—At a conference held in the office of the Health Commissioner on March 10 Mayor Mitchel formally designated the week beginning May 6 as "Baby Week" in New York City. Representatives were present at the meeting from the Chamber of Commerce, the Federation of Women's Clubs, the New York Milk Committee, the National Pure Food and Milk Association, and other similar organizations, and a subcommittee was appointed to prepare plans for the week's observance. Baby contests in all the boroughs and the inspection of the city's institutions for infants and children were among the features proposed.

Charter for Hospital.—The new Broad Street Hospital, situated at 109 Broad Street, New York, has applied to the Secretary of State for a charter, and will be opened as soon as this is granted. The committee in charge has received from various sources in the financial district sufficient funds to permit the equipment of the hospital in a most thorough and efficient manner, and to insure the continuance of the work.

Award Hygiene Prize.—The prize of \$1,000 offered through the American Social Hygiene Association by the Metropolitan Life Insurance Company for the best pamphlet on social hygiene for girls and boys has been awarded to Dr. and Mrs. Donald B. Armstrong of Stapleton, N. Y. The paper will soon be issued by the company as one of the health and welfare series published for the benefit of its policy holders.

Civil Service Examination.—The New York State Civil Service Commission will hold a competitive examination on April 8, 1916, for the position of superintendent of the Suffolk County Tuberculosis Hospital, at a salary of \$2,000 to \$2,500 and maintenance. The examination is open only to physicians who are at least twenty-one years of age and residents of and licensed to practice in New York State, and have had at least three years' experience in the practice of medicine. The examination will cover questions on the practice of medicine, tuberculosis, and hospital management, and experience and training. The hospital is located at Holtsville, L. I., several miles from a railroad station. Persons desiring to enter the examination must file application on blank form E-10 in the office of the State Civil Service Commission on or before April 4, 1916. Blanks may be obtained on application to the commission at Albany, N. Y.

Quarantine Transfer.—Governor Whitman of New York in a speech before the Bronx Board of Trade of New York City on March 11 urged that popular support be given to the measure now before the Legislature by which the control of the quarantine station at the Port of New York will be transferred to the Federal Government.

Public Health Education.—The New York State

Department of Health has opened up a new channel for public health education by securing from five railroads in the State permission to post health bulletins in their stations. The railroads are the New York Central, the Delaware & Hudson, the Lehigh Valley, the Erie, and the Pennsylvania. The department hopes in this way to reach thousands of persons with short talks on the prevention of disease. The first bulletin posted calls attention to the danger of communicating measles, scarlet fever, diphtheria, whooping cough, tuberculosis, and similar diseases, by coughing, sneezing, and spitting, and to the danger in the use of common drinking cups, soiled towels, etc. The second bulletin will be a large map of the State of New York showing in which counties suitable provision is made for tuberculosis patients.

Cost of Insane.—The State Hospital Commission in a recent report states that the care of the 36,664 insane patients in the New York State Hospitals during the fiscal year ending October 1, 1915, cost the State \$6,865,366. The average cost per patient was \$210.89 per annum, or 57.75 cents per day.

Conference of Alienists and Neurologists.—The Chicago Medical Society announces that the fifth annual meeting of alienists and neurologists of the United States will be held under the auspices of the society at La Salle Hotel, Chicago, on June 19 to 23, 1916. Details of the program, etc., may be obtained on application to the secretary of the conference, Dr. W. T. Mefford, 2159 Madison Street, Chicago.

Nurses Graduate.—The annual commencement exercises of the Mount Sinai Hospital Training School were held in the Nurses' Home on March 7, twenty-one nurses receiving diplomas from Dr. Nathan E. Brill.

Typhus Victims.—It is reported from Laredo that Drs. Kolitzky and Rusk, who, with Dr. Baehr, left New York the latter part of January to study typhus fever in Mexico, have contracted the disease.

Dr. Malcolm Seymour of Boston has been appointed State Medical Director of Massachusetts, to fill the position made vacant by the resignation of Dr. Horace D. Arnold.

Professor Girard Dead.—The death was reported recently of Dr. Charles Girard, professor of clinical surgery at the University of Geneva, Switzerland, in his sixty-seventh year.

Centenarians Dead.—Mrs. Mary Hickey, the oldest resident of Binghamton, N. Y., died at her home in that city on March 5 at the age of 108 years. Until a week before her death, it is reported, she spent much of her time piecing bed-quilts, and doing it without the aid of eyeglasses.

Patrick Grogan, who was with Gen. Winfield Scott at the taking of Mexico City in 1847, died at his home on March 6, aged 101 years.

Obituary Notes.—Dr. ANSON L. MARCY of East Orange, N. J., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1873, died at his home on March 9, aged 65 years.

Dr. JOSEPH C. CHARBONNEAU of Worcester, Mass., a graduate of the Victoria University Medical Department, Toronto, in 1874, died at his home, of heart disease, on February 9, aged 65 years.

Dr. BENJAMIN FRANKLIN RICHARDSON of Lynn, Mass., a graduate of Harvard University Medical School in 1886, and a member of the American Medical Association, the Massachusetts Medical So-

ciety, and the District Society, died at his home, after an illness of five weeks, on February 15, aged 53 years.

Dr. MILTON EDWARD BAXTER of Jersey City, N. J., a graduate of the Jefferson Medical College, Philadelphia, in 1909, and a member of the Medical Society of New Jersey and the Hudson County Medical Society, died at his home, from pneumonia, on February 22, aged 35 years.

Dr. DAVID ALLYN GORTON of Brooklyn, a graduate of the New York Hygeio-Therapeutic College in 1858, died, on February 22, after a short illness, aged 84 years. Dr. Gorton was a Fellow of the New York Academy of Medicine, and for many years was editor of the *National Quarterly Review* and also of the *Medical Times*. He founded the Eugenic Society of America and was often called the "Father of Eugenics."

Dr. CHARLES E. SCHOLES of Lynn Grove, Ky., a graduate of the University of Tennessee, medical department, Memphis, in 1892, and a member of the Kentucky State Medical Association and the Calloway County Medical Society, died at his home, on February 3, after a brief illness.

Dr. RICHARD S. GRIMES of Lincoln, Neb., a graduate of the Bennett Medical College, Chicago, in 1878, died at his home, after a long illness, on February 14, aged 63 years.

Dr. JAMES PRESCOTT CHAMBERLIN of South Weymouth, Mass., died at Palm Beach, Fla., from pneumonia, on March 3, aged 85 years.

Dr. WILLIAM B. MCCOY of College View, Neb., a graduate of the Starling Medical College, Columbus, Ohio, in 1897, died on February 21 at his home, from pneumonia, aged 60 years.

Obituary.

WISNER ROBINSON TOWNSEND, M.D.

NEW YORK.

Dr. WISNER ROBINSON TOWNSEND of New York, one of the best known of the orthopedic surgeons in this country, secretary of the Medical Society of the State of New York, and until recently secretary of the Board of Trustees of the New York Academy of Medicine, died suddenly, as the result of an accident, on March 12, aged 58 years. Dr. Townsend was born on Staten Island August 5, 1857, and was graduated from Columbia College in 1877 and from the College of Physicians and Surgeons, New York, in 1880, serving later as an interne at Bellevue Hospital. Since then he had practised continuously in New York. He was at the time of his death associate surgeon to the Hospital for Ruptured and Crippled, consulting orthopedic surgeon to the French Hospital and the S. R. Smith Infirmary, a member of the American Medical Association, the New York State and County Medical Societies, the American Orthopedic Society, and the Society of the Alumni of Bellevue Hospital, and a fellow of the New York Academy of Medicine and the American College of Surgeons.

Dr. Townsend had recently suffered from diabetes and from attacks of giddiness, one of which had, a few days before his death, made it necessary for him to abandon an operation which he was performing at the Hospital for the Ruptured and Crippled. It is believed that during another such attack and while attempting to obtain air, he fell from the window of his apartment to the courtyard below, death resulting instantaneously.

Correspondence.

X-RAY TREATMENT OF RINGWORM OF THE SCALP.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In an article on the "X-ray Treatment of Ringworm of the Scalp" in the *MEDICAL RECORD* of August 7, 1915, Drs. Mackee and Romer describe in detail the "five application" method for depilation of the whole scalp. They state that this method "was originated by Kienböck, and is exceedingly accurate, as is shown by Adamson, Pirie, Sequeira, and many others." This is perfectly true; to Kienböck we owe the clever idea of irradiating the whole scalp in five applications. But I feel that I may claim, not only to have helped to show the accuracy of this method, but also to have rendered it more practicable, and to have introduced it into general use in this country, to be adopted afterwards in France and in America. Indeed, the technique which Drs. Mackee and Romer give as that now in use in Dr. Fordyce's Clinic is precisely that which I first published in 1909, and their description of the method, about which they say "there is nothing original, it being the result of the work of many investigators in the same field," is, with alterations of phraseology, word for word, that which I wrote in my paper to which I have just referred—even to the reproduction of a quaint printer's error, which makes "sine of the angle" into "size of the angle."

To Sabouraud and Noiré above everyone else we are indebted for our present accurate methods of treating ringworm by x-rays; but by Sabouraud's original method depilation of the whole scalp in circular areas necessitated from ten to a dozen applications for each patient. In 1909, having occasion to apply x-rays to a large number of children in an institution, I sought for some way of reducing the number of exposures for each case, and I came upon an article by Kienböck in the *Archives of the Roentgen Ray*, No. 83, Vol. XII, 1907, in which he briefly described his ingenious method of irradiating the whole scalp, in cases of favus, in 5 or 6 applications, in the following words:

Favus: The technique consists in a complete irradiation of the whole scalp, divided into five or six separate areas. Of these, three are in the middle line—the vertex, the fore part of the head, and the occipital region—and one, the temporal region, on either side. A medium soft focus-tube should be used, at a focal distance of 16 to 20 centimeters. The dose should be $6 \times$ to $10 \times$ (3 H to 5 H), a dose which should be reduced in the case of children. The face and neck should be guarded by lead shields, as in the accompanying diagram (Fig. 2). [The figure shows a head with four points marked: 1, toward the forehead; 2, on the crown; 3, on the occiput; 4, just above the ear.]

I proceeded to give this method a trial, but it soon became obvious that in order to render it more accurate for use as a routine treatment of ringworm, it would be necessary to measure carefully the distance between the five central points of the areas of application. This distance was fixed at 5 inches (with the anti-cathode $6\frac{1}{2}$ inches away), and in order to maintain accuracy of direction for each application these points were connected by the guiding lines on the scalp; and converging wooden pegs were fixed round the aperture of the tube-shield, in order to keep the tube at a fixed distance from the area under treatment.

I believe that it was owing to attention to these

details that the method became really practicable and that my introduction of the method, by publication of this technique, led to its adoption by others and to its now general employment.

H. G. ADAMSON, M.D.

17, DEVONSHIRE PLACE, LONDON, ENGLAND.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE "WIND OF THE BULLET"—CONCUSSION OF NERVOUS SYSTEM—SCHOLARSHIPS—ARTIFICIAL LIMBS—EXHIBITION OF INSTRUMENTS, CAMERA AND SPECULUM—LABOR OBSTRUCTED BY OVARIAN CYST—RUPTURE OF BLADDER—CHORIONEPITHELIOMA—VESICULAR MOLE OCCURRENCE.

LONDON, March 19, 1916.

THE war has naturally revived interest in the medical and surgical questions involved. Among them is that popularly ascribed to the wind of the bullet. There is nothing surprising in the fact that men may be made deaf by the explosion of a shell near them, just as occurs from time to time through other sudden and violent displacements of air. The auditory sense is the medium of entrance, but the whole nervous system has to sustain the shock and appears to be affected simultaneously. In severe cases concussion of brain or spine may be caused, and it is said many soldiers have been killed without being actually struck by a bullet; at any rate, many have been found insensible and have continued in that state for hours or even days without any wound or any outward mark. On the other hand, there are numerous instances where slight but definite injury to the surface accompanies the most serious symptoms of a general or internal character.

Twenty-five scholarships and exhibitions aggregating about £2,000 in value will be open for competition in May at the University and Kings' Colleges and the East London College. Fourteen, aggregating about £1,200, will be offered in July at the several medical schools.

At a conference in connection with the Exhibition of Artificial Limbs organized by Queen Mary's Auxiliary Hospital, Sir William Watson Cheyne, president of the Royal College of Surgeons; Sir W. R. May, director-general Royal Naval Medical Service, and Surgeon-General Russell, representing Sir Alfred Keogh, Director-General Royal Army Medical Service, were the leading speakers. The chief points emphasized were the importance of fitting the artificial limbs as early as it was possible for them to be worn and of instructing the recipients as to their use. Sir A. May said a month's delay might throw the patient back a year. It was referred to orthopedic surgeons to report on the type of limbs that should be supplied in view of the work to be done. The awards of the committee of orthopedic surgeons were announced.

At the Obstetrical Section of the Royal Society of Medicine Dr. H. Spencer showed a "speculum-camera," a combined Fergusson speculum and camera fixed together by a catch, for taking photographs of tumors and other conditions of the vagina and cervix. Illumination was obtained from six electric lamps surrounding the lens; an exposure of 20 to 30 seconds sufficed. Dr. Spencer also showed a wire-fed tubular needle for use in closing vesico-vaginal fistulæ. This was a modified cleft-palate needle, and he said he had used it for several years. Another instrument he showed was a needle-

holder for vaginal hysterectomy and deep pelvic work, designed for ligaturing in deep confined spaces. It was held by a slot at an acute angle with the handles, and as this slot was not extended to the end of the jaw, could be introduced and withdrawn in the same direction by one instrument.

Dr. Salisbury then read an account of three cases of labor obstructed by ovarian cyst. In one the abdomen was opened, a dermoid the size of an ostrich's egg withdrawn from the pelvis, not without some difficulty, and it was ruptured in the process. A dead child was delivered *per vias naturales* with axis-traction forceps. A good recovery followed. In another case the midwife sent for a surgeon, but before he arrived a living child was born weighing 7½ pounds. The patient was removed to hospital, the abdomen opened and a semi-solid multilocular cystadenoma of the left ovary 2½ pounds in weight removed. It had previously ruptured and much blood and mucoid matter was present in the peritoneal cavity. Patient recovered without interruption. In the third case the patient was admitted to hospital in labor. There was a hard mass in Douglas' pouch, diagnosed as ovarian dermoid. The abdomen being opened, the mass was not very accessible and cesarean section was performed by which a living child was delivered. The tumor was then removed and the patient made an uninterrupted recovery.

Dr. Spencer said the first case was treated in the way he had advocated for 18 years, and yet he considered many unnecessary cesarean sections had in that period been performed. He thought it was time they were discontinued for such cases. In the third case pushing up the tumor in the Trendelenburg position, as shown by Bossi to be quite easy, was the best treatment. The knee-chest position under anesthesia might be better still and should certainly be tried before resorting to cesarean section. As to the size of the tumor, it was likened to an orange and to a cocoanut. It was important as to tumors obstructing labor to know the exact size. Liking them to familiar objects was convenient during clinical examination, but when removed by operation their dimensions should be recorded precisely in inches or centimeters.

Dr. Frances M. Huxley read a case of fatal rupture of the bladder during the puerperium. The patient was delivered by forceps. The bladder was not catheterized previously, but all went well until the ninth day, on which, after a stretching movement of the arm a sudden violent abdominal pain came on with vomiting and collapse. Next day she was admitted to hospital with well-marked signs of peritonitis and fluid in the cavity. No urine had been passed for 30 hours; 40 ounces withdrawn on admission and 34 ounces 8 hours afterward. Stimulants were given, but the case steadily progressed to a fatal end. At the post-mortem there was found rupture of a thin-walled bladder forming a jagged slit at the summit of the fundus; no bruising nor any signs of sloughing. It seems almost certain from the history that the rupture took place on the ninth day when the patient made the sudden stretching movement. Forceps had been used, after which atony of the bladder remained, and it was distended when the sudden contraction of the abdominal muscles sufficed to cause the rent in the wall, at the site of which the specimen showed thinning.

A short communication from the president was

read on chorionepithelioma following vesicular mole, and these questions were added to the paper: (1) With what degree of frequency does vesicular mole occur more than once in the child-bearing period of any woman? (2) What is the earliest period at which it is found well marked after the expulsion of such mole? (3) Does it perforate the uterine wall with any degree of frequency before expulsion of the mole? (4) What constitutes the difference between malignant vesicular mole and benign cystic degeneration of the chorionic villi? Might the resisting power of the uterine wall be a factor of some importance? Dr. Routh remarked that 30 years ago if a woman had a vesicular mole a recurrence was possible if she again became pregnant. His experience did not support this, for he had never met with a case of such recurrence.

2. Neurological Surgery in a War Hospital. Elliott C. Cutler.
3. The Present Status of Gallstone Diagnosis by the Roentgen Ray. Frederick W. O'Brien.
4. Bridging a Gap in Out-Patient Service. Hilbert F. Day.

1. Relation of Dulness to Cardiac Outlines.—George Cheever Shattuck has attempted by teleoroentgenography to check ordinary light percussion, using it objectively with reference to sound, disregarding resistance, and abstaining, as far as possible, from allowing knowledge of anatomy or other evidence to influence the result. Before taking the x-rays, the outlines of slight diminution of resonance (*i.e.* slight dulness) were determined by light percussion and marked with wires stuck to the chest wall with adhesive plaster. The accompanying pictures were taken from x-ray plates taken with the tube at 6 or 7 feet from the plate to avoid magnification by giving nearly parallel rays. The plate lay against the patient's chest, the tube was behind him. The patient was standing and the pictures were taken at mid-respiration, not full respiration, because the latter alters the relation of the heart to other structures. Shattuck's outlines of dulness do not correspond with the silhouette outlines of the heart, as shown in the x-ray. The reasons for this are: first, relative dulness near the heart may be produced by structures other than the heart. Second, slight cardiac dulness, even when the heart is of normal size, generally extends toward the axilla, so that outlines which follow closely the borders of slight dulness fall of necessity upon a curved surface. He considers that the following conclusions seem warranted regarding ordinary percussion: First: It easily reveals gross abnormality in cardiac dulness to right or left. Second: It may suggest slight abnormalities which must then be confirmed or disproved by other means. Third: When percussion indicates slight cardiac enlargement, or no enlargement, palpation, auscultation, blood-pressure, or history may provide further evidence of importance which can be used to check the results of percussion. Fourth: When doubt still remains, teleoroentgenography or the orthodiagraph may be of service; but it should be remembered that variations of heart size are dependent on many factors, and that the average man does not exist. Moreover, the errors of these methods in the hands of one who does not appreciate their difficulties, when applied to the heart, are large. Fifth: Percussion is especially unreliable for finding slight enlargement of the aortic arch, for determining the level of the apex, and for discovering hypertrophy of the left ventricle when

there is little or no dilatation. Palpation in the left lateral position is often helpful for solving the last two problems, and accentuation of the aortic second sound, or increase of blood pressure should not pass unobserved. Sixth: It is not worth while to attempt by ordinary percussion methods to make a silhouette outline of the heart. It is better to note the relations of dulness in terms of interspaces and anatomical lines, and to compare the findings with a subjective standard based on experience, than to judge of enlargement by measurements of ordinary percussion outlines and comparison of them with orthodiagraphic standards. Seventh: The attempt to make silhouette outlines of the heart by means of special methods of percussion has shown, in the hands of a few, results which are good but more or less uncertain.

3. The Present Status of Gallstone Diagnosis by the Roentgen Ray.—Frederick W. O'Brien gives a résumé of a great part of the literature on this subject extending from March, 1913, to September, 1915. The consensus of opinion from such writers as Holland, Cole, George, Case, Pfahler, and Beck of this country, and Mathias and Fett, Haenisch, Edling, and Panzer of Europe, is that in at least 50 per cent. of the cases of gallstone condition, the stones can be diagnosed, and well, by the Roentgen ray. O'Brien gives a description of his technique in his Roentgen ray work, and says that success in gallstone diagnosis even may extend to the method used in the dark room. A satisfactory developer is of the greatest importance, and plates that are too dense to be read may be reduced and in that way gallstone shadows detached in the process of reduction that would not be likely to be found in any other way. A description of the various types or kinds of stones and the interpretation of their shadows is given. The Roentgenographic appearance of gallstones will vary according to the amount of lime salts present. Differentiation must be made from shadows caused by food remnants, bismuth remains from treatment or residue from a meal, calcified costal cartilages, calcified mesenteric glands, and, chiefly, renal stones. When no direct evidence of gallstones is found, a negative diagnosis should not be rendered until the indirect evidence of gall-bladder disease has been looked for by serial plates and Roentgenoscopy. This done, a positive or negative diagnosis of gallstones may be made with safety.

7. Bronchiectasis. Earl H. Mayne.

1. Gall-Bladder Diseases.—Charles H. Mayo, in discussing the etiology, symptoms and treatment of this condition, says that the etiology of diseases becomes clear only as the bacterial or toxic causation is appreciated. Symptoms are the expressed reactions of the protein cells of the body against disease by infection or toxin in developing immunity. Undoubtedly the greatest advance in modern medicine is the knowledge that practically all diseases are the result of protein changes, usually from infection, and that some degree of bacteriemia exists in all infections. The very existence of life itself means a constant fight against its destructive agents until we finally succumb to them. Mayo further speaks of the work of Rosenow in reproducing gall bladder disease, and even stone formation in animals, by means of strains of bacteria grown from diseased

gall bladder and injected into the animal's blood. This is called specific selective affinity. Strains developed from the gall-bladder carried through artificial media develop gastric ulcer in an increasing proportion. It is known that gallstones long since removed from the bladder may retain living bacteria for years. He shows in what different ways or by what avenues the infection reaches the gall bladder, and gives the symptoms of the various pathological conditions that may result. In his treatment of gall-bladder conditions he advises careful, easily digested diet; taking hot water before meals as of benefit in cholecystitis by starting the emptying of the gall bladder and the flow of bile before food enters the stomach and gas formation begins, leaving the gall bladder with a temporary reserve capacity within the limits of unconscious distension following the meal. A knowledge of the structures and function as well as the mechanics of delivery is essential to the proper surgical treatment of these diseases. The following conclusions are presented: Cholecystitis is an infective disease of the gall bladder. The bacteria are in the tissues of the gall bladder. Infection may be mild, acute, chronic, or recurring. Gallstones may occur in mild infections. Cholecystostomy or cholecystectomy without stones or local evidence of infection will not improve the symptoms for which the operation was made. Gallstones may cause mechanical obstruction. Cholecystostomy (with removal of stones, if present) gives high percentage of cure only if the infection has subsided or has been maintained by stones. Cholecystectomy with or without stones in diseased gall bladders or existing cholecystitis gives a high percentage of cure. Reflex gastric symptoms are caused by the infection. The infection may, through local peritonitis, cause adhesions to bowels or stomach or of the liver to the abdominal wall. Symptoms of mild gastric trouble may be nearly constant, increase with exacerbation of infection and subsidence of attack, much like those of ulcer. The etiology may be a small local focus primary in the mouth or secondary in the appendix. Typhoid bacteriemia may be the etiological factor.

5. Recovery of *Streptococcus Viridans* from New York Street Dust.—William C. Thro says that in view of the almost universal presence of *Streptococcus viridans* in infections of the oral cavity and of the respiratory tract and its almost constant presence on the tips of the roots of teeth extracted from patients with chronic infectious arthritis, the recovery of this particular organism from the out-of-door dust seems a matter worthy of investigation. That this dust is inhaled in large amounts no one will deny. *Streptococcus viridans* has also been isolated from New York street dust by the New York Board of Health, as was stated in the *Weekly Bulletin*. In the investigation carried on by Thro the dust was collected on a balcony at the level of the second floor of a building on First Avenue near Twenty-eighth Street. In the beginning several methods were tried for placing the material on the culture media, but the third method was the most successful. In this the dust was swept off the stone columns and the top rail of the balcony, and after being diluted in normal saline, was streaked on plates of North's media. After twenty-four hours' incubation the colonies were fished off and placed on slant tubes of North's media. The cultures were stained later with Gram stain. Several other microorganisms were found, but no attention was paid to them. Of the streptococcus-like colonies that were fished off and found to be Gram positive, seven produced green pigment in human blood agar plates. Of these, two had very long chains up to eighty in number, but the remaining strains occurred in twos, fours, and groups

None of the strains of cocci were encapsulated. Other tests followed out proved these cocci to be of this group. Six of the strains were injected subcutaneously, as broth cultures, into white mice, but all of the mice recovered. One strain was inoculated subcutaneously into a half-grown white rat, which died in sixteen hours. The finding of *Streptococcus viridans*, a very common bacterium in infections of the mouth cavity and of the respiratory tract, seems then to have been demonstrated beyond a doubt.

3. Hay-Fever: Its Cause and Prevention.—William Scheppegrell states that from the standpoint of the number of patients affected, hay-fever ranks among the first of the non fatal diseases. He describes the symptoms, which are only too well known, and under diagnosis says that some physicians still believe that hay-fever is a local manifestation of some constitutional condition, notwithstanding that the majority of patients with similar conditions have no manifestations, and that when pollen is not present, they do not occur. The etiology of this condition was unidentified for a long time. When patients developed an attack in the neighborhood of weeds, the conspicuous goldenrod was at once suspected, and the ragweed with its insignificant green flowers unobserved. Again, the goldenrod is an insect fertilized plant, while the ragweed is a wind fertilized plant. Goldenrod is responsible for only a small percentage of cases. Besides the ragweed, of which two main varieties, the wormwood and the giant, are the most important, there are ten other plants indigenous to the Southern States, the pollens of which produce hay-fever. They all have the same characteristics: they are wind-pollinated; very numerous; flowers are inconspicuous, with no bright color or scent because insects are not to be attracted, and the pollen is formed in great quantities. The development, duration, and conclusion of hay-fever are synchronous with the pollinating period of the ragweeds, and any elevation under 6000 feet may produce the weeds and the disease to susceptible persons. It would appear that there is a wide difference in the degree of susceptibility of different individuals to the pollen. An attack would develop, therefore, only when the exposure overcomes the resistance of the subject and only to this extent. When the attack has been developed once, clinical experience shows that the susceptibility of the patient is increased, indicating that resistance has been lowered. The manner in which pollen excites reaction is dif-

ferent in individuals. Thus, any pollens with prickly coatings fail to produce irritation, while the pollen of ragweed is without spikes but develops marked reaction. It has been asserted that the pollen, under the influence of the nasal secretion, germinates and sends out its germ tubes, thus producing the irritation. This germination takes place only in the presence of sugar, which is absent in the nasal secretion, and is inhibited by sodium chloride, which is present. The process of germination usually takes about two hours, while the local reaction of hay-fever may take place in a few minutes. The majority of hay-fever patients present no unusual abnormal intranasal condition except during the attack, and operations for nasal obstruction, unless indicated for other reasons, have been seldom successful in their intended results, and are rarely advisable. Any of the various treatments for hay-fever have not met with conspicuous success, and the sure means will be in the eradication of the weeds causing the disease. The American Hay-Fever Association has given its first attention to the eradication of ragweed, and the United States Department of Agriculture has assisted and is furnishing valuable information for this work. In New Orleans an organized campaign is being carried on through the State Board of Health, the City Public Works Department, and the Women's Civic League to rid the city of ragweed. The statement that a town is free of hay-fever will prove an advertisement that will easily repay the cost of destroying the hay-fever producing weeds.

5. The Treatment of Hay-Fever with Calcium Salt.—Harold Wilson, attracted by the reports of Emmerich and Loew on the very favorable results secured by them from the prolonged administration of calcium chloride in the treatment of hay-fever, began to make a trial of this drug for this condition during the season of 1915. Twenty-six patients were treated; of these, twenty-two received the calcium chloride exclusively, and four patients, who had been under treatment by means of pollen solution injections, were given the drug when their hay-fever symptoms began to develop more or less severely. Twenty-two patients gave a positive ophthalmic or cutaneous reaction to ragweed pollen; four gave a negative reaction to ragweed. Treatment began in June with seven patients; in July with four; in August with fifteen, and in September with two. No patient took the drug for more than eight or ten weeks before the expected attack, and in most cases the period was much more brief. In some of the most favorable cases here reported, the relief came almost at once, or after taking only a few doses. For most patients the prescription was as follows: Calcium chloride, crystals 100 grams, distilled water 500 c.c. A teaspoonful in sufficient water was ordered during or after each meal. This gives the patient about 3 grams of calcium chloride daily. It was not observed that this amount of the drug was followed by any marked bodily disturbance; in fact, much larger doses can apparently be taken with entire safety. As a result of the season's experiments he has made the following deductions: 1. Some hay-fever patients taking not less than 3 grams of calcium chloride daily, even for a short time, are practically relieved from all hay-fever symptoms. 2. Calcium chloride may be taken in doses of 3 grams daily for an indefinite time without any apparent injury. 3. It is not indispensable in all cases for a hay-fever patient to take calcium chloride over a long period of time in order to secure relief. 4. Calcium salts may be given, even when the nature of the patient's sensitization is not known. 5. The clinical results from the administration of calcium chloride in cases of hay-fever are such as to warrant its further trial.

6. The Spleen.—William J. Mayo for many years

when doing abdominal operations, has made a careful manual examination of the abdominal contents when no risk to the patient was involved. At times careful physical examination by percussion has revealed apparently the area of splenic dulness, but on the opening of the abdomen the fact showed how fallacious percussion had been. He especially draws attention to the association of the spleen with the liver and to certain conditions of the blood. The spleen is closely associated with the liver in function, deriving its blood supply from the same source, the celiac axis, its vein becomes part of the portal circulation. Investigation leads to the conclusion that the function of the spleen is not only to remove from the blood bacteria and other toxic agents, but also to conserve the food values of broken-down blood corpuscles, especially red cells, sending their remnants to the liver for elaboration into energy-producing substances. There is increased hematin and a relative increase of leucocytes in the splenic vein. The spleen is a sieve selecting certain substances—parasitic, toxic and products of degeneration—and, unable to deal with them, passes them on to the liver for conservation. That the liver may adequately maintain this important function, it has been given the power of regeneration. It is interesting to note how the spleen is controlled in its function. That the spleen does not have an important internal secretion is shown by the fact that its removal does not deprive the body of any important constituent; that it is not under the complete control of the nervous system as shown by its scanty supply from Auerbach's plexus. But the spleen contains a considerable amount of non-striated muscle fiber, and it is probable that this muscle has an important function and possibly is responsible for the digestive rhythmic change in the size of the spleen. The presence of this muscle tissue gives important evidence of the primary relationship of the spleen to the digestive system. The relation of the spleen to the blood has been known a long while. All the red-blooded animals possess a spleen. The blood pictures of the various anemias are often the reproductions of the normal blood of lower animals in which a shorter heredity has given less fixed characteristics than in man. The spleen seems to become the graveyard of worn-out corpuscles, especially of red cells. It probably does not act on its own initiative, but as though the red cells were sensitized some other place in the body and destroyed in the spleen. It would appear that the excess of splenic tissue thus formed produces a hypersplenism, and unnecessary destruction of red cells. Mayo refers to the cure of anemias from various causes by the removal of the spleen, and says that this suggests that the spleen, not necessary to prolongation of life, and not causing disease on its own account, is the one link on an otherwise fatal chain which can be easily and safely broken. As the removal of the tonsil may prevent generalized infections, so splenectomy may cure disease conditions of the nutritive system, especially those of the liver and blood. He divides enlargements of the spleen into four groups: (1) new growths, not discussed here; (2) infections in which there may or may not be marked improvement, and two cases are cited of syphilitic enlargement, in which removal of the spleen cured the anemia and produced general improvement; (3) splenic enlargement associated with hepatic disease, in which the common forms of cirrhosis of the liver may be divided into three classes: portal cirrhosis, biliary cirrhosis, and mixed types; and relief may be gained through splenectomy, although in his own cases he considers it too early to know the end-results; (4) the blood, as represented by splenic anemia which, clinically, is an entity. His experience in the removal of the

spleen in three cases of Gaucher's disease—a form of splenic anemia—has shown that in the earlier stages the condition is cured by splenectomy. He mentions nine operations done at his hospital for hemolytic jaundice, and further says that he knows of no other operation which gives more brilliant or striking results. With reference to pernicious anemia, of which he reports operations on nineteen patients, he feels justified in performing splenectomy in selected cases. First transfusion of blood may be necessary.

8. **Precordial Pains of Cardiovascular and Extracardiac Origin: Clinical Varieties, Etiology, and Therapy.**—Selian Neuhof. (See MEDICAL RECORD, January 15, 1916, p. 123.)

9. **Certain Aspects of Infantile Paralysis.**—Lovett and Martin present an account of a combined physiologic and orthopedic study of certain phenomena of infantile paralysis. Their work has been done under the direction of the State Board of Health of Vermont, and carried out both in Vermont and Boston. The inquiry was started in the late autumn of 1914, the Rockefeller Institute, through Dr. Simon Flexner, taking charge of the epidemiologic end of the inquiry and opening a laboratory in Burlington, while to Lovett was assigned the therapeutic side, and the physiological department of Harvard University aided in the study, and a system of muscle measurement was devised by Martin. The general thesis of their paper is as follows: The observations in about 300 cases in Vermont have shown that in all cases, old and recent, infantile paralysis has been found in most muscular groups not to be a paralysis in the sense of a complete loss of power, but a weakening of these muscles. Now weakened muscles can, as a rule, be made stronger by judicious exercise, just as can normal muscles. The therapeutic problem, therefore, requires the closest possible study of such muscles and of the therapeutic means by which their individual power may be increased. It is a very important matter to the parents of a child with a gastrocnemius muscle reduced to only 20 per cent. of its normal power whether this muscle ultimately returns to 40 per cent. or 90 per cent. of its normal strength. At the outset of the Vermont work, muscles were classed as normal, partly paralyzed, or totally paralyzed. With the realization that partial paralysis was the usual form of affection, it became imperative to have some scale by which to work out what should be a precise and improved treatment. The muscle test offers a practical quantitative scale by which the effects of modifications of treatment may be studied week by week and month by month. The test devised consists of estimating the strength of the various muscular groups by means of spring balances. Standard positions for each group are chosen, so that the same position is assumed on consecutive observations. The strength test is based on the patient's power to hold a position against the pull of a spring balance, and the resistance registered on the balance in the standard position represents the muscular strength. The pull is exerted from a sling attached to the member to be tested, and the line of pull is at right angles to the long axis of the limb. The balance is hooked into the sling, and the other end held by an assistant. Two tests are taken and the larger reading recorded. The results have been surprisingly accurate, and consecutive readings on the same patients have been used to check up this accuracy. The muscle groups tested are twenty-two in number for each side: in the leg, plantar and dorsal flexion and inversion and eversion of the foot, flexion and extension of the knee, etc., and in the upper extremity twelve tests. Studies were done on 177 patients, on whom 13,000 observations in 400 series

were made, forty-four different muscular groups, twenty-two on each side of the body, being available for study. They found that the muscular affection is much more widespread than ordinarily supposed, thus corresponding closely to the pathology as observed of late years. There is also a predilection on the part of total paralysis for the lower leg, and in the observations on the 150 cases the peroneal and anterior tibial muscles showed of all the muscles the largest incidence of total paralysis. It has appeared that the strength of affected muscles tends on the whole to remain stationary or to improve, and that a loss of strength is not to be expected, and when it occurs it should be investigated. Fatigue, ill-health, and over-use of the muscles influence the rapidity of improvement as well as hot weather conditions. As to the effects of treatment, in the time available for observation the following facts appeared: The chance of improvement in affected but not totally paralyzed muscles under expert treatment by muscle training was about 6:1, under supervised home exercises 3.5:1, under home exercises without supervision 2.8:1, while untreated affected muscles in these patients showed an improvement ratio of 1.9:1. These patients were nearly all affected in 1914, and represent cases at the end of the first year. They are all from the Vermont Group and were treated there.

4. Some New Forms of Occupational Dermatoses. R. Prosser White.
5. Some Experiments with the Simpson Arc Lamp. J. H. Sequeira.
6. A Brief Account of a Method of Providing Baths for the Soldier in the Field. H. Norman Goode.

1. **Hunterian Lecture on Ulcers New and Old.**—In this lecture, delivered at the Royal College of Surgeons of England on February 4, Sir John Bland-Sutton describes duodenal ulcer, its situation, and some of its complications. He also points out two unusual features common to this type of ulcer, first, that some of the most troublesome ulcers in the pyloric region can neither be seen nor felt in the course of a gastrojejunostomy, and a small duodenal ulcer can only be detected when it involves the peritoneum and produces a tell-tale scar. Second, in all regions of the body open to observation a chronic ulcer is liable to become cancerous, especially between the thirtieth and fiftieth years; this is the age-incidence of duodenal ulcer, but this cancerous change in duodenal ulcers has never been proved. With reference to the jejunal or peptic ulcer, occurring after gastrojejunostomy, he says a consideration of the structural alterations of the jejunum in the neighborhood of the new stoma resulting from this operation leads to some conjectures of interest. There are no valvulae conniventes in the first four or five cm. of the duodenum, and its wall is thinner than in the remaining portion. A remarkable transformation occurs in the jejunum when the escape of chyme from the stomach is transferred, in consequence of gastrojejunostomy, directly into the jejunum. The wall of jejunum receiving the impact of chyme ejected through the new stoma becomes attenuated, the valvulae disappear, and the jejunal walls assume the peculiarities of the supra-ampullary segment of the duodenum. This change entails a liability to ulceration so common in duodenum. After giving an account of indirect operations on the viscera and the technique of pylorotomy, he summarizes as follows: Since the treatment of duodenal ulcer passed into the province of surgery it has become the

routine practice to perform gastrojejunostomy for its relief in the hope that by diverting the chyme through the new stoma into the jejunum the ulcer will heal. If the pylorus is obstructed by the ulcer the results are usually good, because the chyme must pass through the new stoma; but when the pylorus is patent the chyme flows through it and in some instances ignores the new route. The efflux can be watched with the help of an opaque meal and x-rays. It is better whenever practicable to excise the pylorus with the ulcerated portion of the duodenum and rejoin the stomach and duodenum on the principle of an end-to-end anastomosis. If this method could be made safe gastrojejunostomy for the relief of chronic duodenal ulcer with an unobstructed pylorus would soon be abandoned. Experience proves that posterior gastrojejunostomy with an obstructed pylorus is a beneficial operation, in spite of the risk the patient runs of getting a new ulcer for an old one. The new ulcer has been evolved in this generation by alterations in the environment of the jejunum brought about by surgery.

2. **Trench Nephritis.**—In May last the Medical Research Committee, at the request of the Director-General of the Army Medical Services, made arrangements for a number of cases of trench nephritis to be investigated in wards at the St. Bartholomew's Hospital section of the First London General Hospital, under the care of W. Langdon Brown, who reports the results of the study of fifty-eight cases, although 100 cases were taken care of. He calls this condition "epidemic nephritis," and says that while it could be called "trench nephritis," he has had cases occur in orderlies from base hospitals and others who have not been in the trenches. Exposure has always supposed to have been an important cause of this condition, yet, while the troops were enduring cold and exposure during the bad winter of 1914-1915, there were but few cases of nephritis then. It was not until the weather was better that the disease assumed epidemic proportions. Brown doubts very much if more exposure damages healthy kidneys, but does consider that it will exacerbate chronic nephritis. A point deserving consideration is the comparative rarity of the disease among officers. While many reasons are offered and discussed as the probable cause of this condition, Brown seems inclined to accept the theory of specific infection. Tests were made in the laboratory which bore out this theory. Among the symptoms he cites edema, and the frequency of dyspnea as early symptoms; there was a slight, irregular temperature in the earlier stages, sometimes prolonged where recovery was slow, and cough. There was great variability in the amount of urine secreted. Often it was markedly increased while the disease appeared to be fairly acute—i.e. there was hypostenuria or inability to secrete a concentrated urine. The urine was sometimes bright red with blood, sometimes merely smoky, and often chemical and microscopical tests were needed to detect the blood. He was struck with the fact that in some cases blood continued to be poured out in some quantity long after all other symptoms had subsided, as though the damaged kidney continued to leak blood rather than the presence of a hemorrhage inflammation of the kidney. Casts were present in all but three cases; usually a mixture of epithelial, granular, and hyaline. Blood casts and fatty casts were uncommon, as also were crystals. Catheter specimens showed a rarity of organisms. Albumin was, of course, present. His treatment of these cases consisted in a diet poor in nitrogen, on account of the nitrogen retention, but liberal in carbohydrates and fats for limited periods in the smaller stages. Sometimes this proved of benefit, again it seemed to make little or no difference.

Brown draws the following conclusions from his study and investigation of this so-called trench nephritis: 1. These cases are true examples of acute nephritis, as shown by (a) the combination of edema with albuminous urine containing casts; (b) the nature of the proteins in the urine; (c) the tests for renal permeability; and (d) post-mortem evidence. 2. The cases have been too prevalent to be merely accidental, and the close similarity of the symptoms suggests a common cause. 3. Exposure, water-supply, metallic poisons, or intestinal toxemia can be excluded as the cause. The prolonged cases showed a high percentage of positive Wassermann reactions. 4. The curve of incidence both in this war and in the American Civil War suggests an infective agent, as does the unequal degree to which the different units were affected. This is supported by the extent to which the glomeruli were involved, as shown by the chemical tests and the post-mortem evidence. 5. So far bacteria have not been found responsible for the infection, though more positive evidence might be obtained from earlier cases. Results suggestive of a possible filter-passer have been obtained, but they are not conclusive. The point of entrance of the infection is possibly the tonsils and upper air-passages. Suggestion is made that there is a specific organism responsible which resembles but is not identical with that causing scarlet fever. 6. The outstanding clinical features of the epidemic are: (a) The frequency with which shortness of breath occurred at the beginning; (b) the great variability in the duration; (c) the tendency to remission and relapse; and (d) the ultimately favorable prognosis in the majority of the cases.

4. **Some New Forms of Occupational Dermatoses.**—R. Prosser White gives an account of some new forms of dermatoses occurring as a result of the war. The increased demand for the production of trinitrotoluene, nitrate of ammonium, and nitroglycerine as ingredients for high explosives for military purposes, has produced an increased number of workers in these materials, with the resultant skin conditions. He describes trinitrotoluene dermatitis as seen on the hands, but it may occur on any exposed parts of the body, or wherever the fine powder falls and sifts through the clothing. The earliest rash is a superficial erythema, but as usually seen consists of patchy, irregular-shaped, slightly raised areas of redness varying in size from a pin-head to a shilling, between which is the normal-colored skin. These spots coalesce by spreading at the edges and by the formation of new centers. The parts most affected are the hands and arms, the neck, the lower part of the abdomen, the inside of the thighs and scrotum, the back above the buttocks, the calves, and between the toes. On exposed and constantly irritated surfaces such as the arms, a continuous sheet of redness ultimately develops. The skin becomes greatly thickened and takes on what Sabouraud calls "secondary lichenification." Moisture appears to dispose toward the production of vesicles, which quickly rupture by chafing, especially on the thin epidermis of the scrotum and thighs. In this region the inoculation of pyogenic organisms readily produces superficial ulcers. The character of the desquamation follows the ordinary rules and depends upon the severity of the inflammation and the thickness of the epidermis. Crusting is slight. Hot weather and consequent sweating only increase the trouble. In the nitrate of ammonia dermatitis, the symptoms are slight, consisting chiefly of a mild erythema. In stomonal dermatitis, while there is an erythema, the parts are itchy, and cracks form, into which the powder falls, causing excessive irritation and burning. In all

these cases White first prescribes a paint composed of camphor, carbolic acid, perchloride of mercury, picric acid, and alcohol, to be applied by a swab or brush. Proper ointments are applied at night. Another interesting condition described is wet winders' acroasphyxia, in which the distal ends of the fingers and thumbs become anesthetised, due to a preparation containing formaldehyde, and used in what is termed the "conditioning" of thread.

6. Antenatal Clinics and Prematernity Practice at the Edinburgh Royal Maternity Hospital in the Years 1909-1915. J. W. Ballantyne.

1. Observations on Gunshot Wounds of the Head.—H. M. W. Gray states that the principles and practice carried out, almost without exception, by surgeons at work in the military hospitals mentioned are as follows: That infected gunshot wounds of the skull and brain require more careful consideration and prompt attention than similar wounds of any other part; that we can combat and prevent sepsis best by early and complete operations; that we can prevent permanent disability in most cases by systematically removing foreign material or displaced bone from the surface or substance of the brain whenever these are accessible to legitimate surgery; and further, that, by these precautions, the immediate results in the saving of life and more rapid restoration of function, when that is possible, are better than those obtained by more conservative procedures. He notes that they have seen many cases with extensive superficial injuries with little or no damage to the brain, and, on the other hand, many cases in which an insignificant-looking wound of the scalp and skull was associated with most extensive injury to the brain. The size or condition of the wound, therefore, is no indication of how the case will behave. One is told that edema of the brain, and shock or concussion accompanying a serious injury, are such that operation at an early stage is dangerous. Yet, many patients brought to a clearing station in practically a moribund condition, after immediate operation, in a few hours are able to speak intelligently and to take food. In serious cases delay does not seem advisable. Attention is called to the value of local anesthesia for many of the cases. The solution need be injected only into the scalp tissues and pericranium. The skull, dura, and brain will thereafter be found to be insensitive. If adrenalin is mixed with the solution, bleeding of the scalp is reduced to a minimum. After consideration of these facts, more attention is shown to be needed to the probable mechanical effects of the injury and the potentialities for infection than to worry much over the presence or absence of definite symptoms. The lesion is a traumatic one, the possibility of sepsis is great, and things should not be left to chance or until the development of some particular symptom. Among the points given are that there may be multiple injuries, therefore, always have the whole scalp shaved. The force causing the injury is usually very circumscribed, and its effects likely to be localized in the immediate neighborhood of the part which has been struck. Such localized forces, if they have been great enough to cause depressed fracture of the inner table, result, usually, in definite injury to the brain, which asserts itself by immediate or remote cerebral disability. This may occur in pronounced form, although

the dura is uninjured; in rare cases it has occurred even when no fracture of the external table has been seen. Experience has shown that a properly conducted, complete operation gives better immediate results, and tends to prevent troublesome sequelæ more surely than an incomplete one. Death is due, practically in all cases, to the effect of sepsis on the injured brain. Efforts, therefore, must be directed to the elimination of sepsis, and excision of the infected parts is the most rapid and certain way of doing this. Proper technique is essential to success. The objects of treatment can be summed up as follows: 1. To prevent or remove infection, thereby preventing further destruction of tissue. 2. To establish diagnosis in some cases of doubt. 3. To remove all sources of irritation to the brain, if this can be done without causing further serious damage to it. One cannot undo the initial surface wound or cerebral lesion, but one can try to procure a condition which will allow healing to occur more rapidly, more normally, and with less permanent impairment of function. 4. In any case to procure rapid healing of the superficial parts, provided that the brain is safe.

6. Antenatal Clinics and Prematernity Practice at the Edinburgh Royal Maternity Hospital in the Years 1909-1915.—J. W. Ballantyne has given an elaborate account of this work covering the years mentioned and has deduced the following conclusions regarding prematernity work in a maternity hospital: 1. A prematernity department is an essential part of a properly-equipped maternity hospital, and it ought to consist of a pregnancy ward, antenatal clinics, and of prenatal nurses (in the extern work). 2. Among the good results coming from it may be reckoned the saving of lives (maternal and infantile), the relief of maternal suffering, the possibility of supervising antenatal hygiene, and the teaching of the normal and abnormal conditions of pregnancy both to students and to post-graduates. 3. The maternity hospital which has such a department will probably have a higher death-rate, for it will inevitably attract to itself cases of a very grave type; but these patients must be treated somewhere, and they will have a far better chance of recovery in the prematernity ward with adequate nursing and skilled medical treatment than in their own homes. 4. The diseases which will be specially benefited by prematernity treatment will probably be albuminuria, eclampsia before the supervention of labor, hyperemesis, chorea, acidosis, threatened abortion, cardiac complications, anemia, chlorosis, hydramnios, phlebitis, pyelitis, and the *ante-partum* hemorrhages before the onset of labor; but the ward will also offer advantages to patients waiting for the induction of premature labor on account of pelvic contraction or previous dead-births from any cause. Less common indications for admission will be found in melancholia, alcoholism, jaundice, gastric ulcer, myxedema, mucous colitis, phthisis, recurrent abortion or fetal death, hematuria, injuries, etc., and, indeed, many other uses for the ward will be found after its opening. 5. Further benefit will accrue from the establishment of a well-equipped laboratory, in which the finer methods of clinical investigation can be carried out, as well as by the securing of the services of a pathologist skilled in the special morbid anatomy of the fetus, embryo, placenta, membranes, and liquor amnii.

Berliner klinische Wochenschrift.

January 24, 1916.

Ogival Palate and Adenoids.—Lublinski affirms that now and then children with adenoids fail to improve after not only the nasopharynx, but the nose itself has

been cleared out. That is to say, the child continues to breathe through its mouth, with all the resulting damage to ear, larynx and trachea. But the reason is obvious, for examination in such cases will reveal a high narrow palate in place of the normal broad, low one. The higher and steeper this palate, the narrower the nose, and the higher its floor. As a result air which enters such a nose enters with difficulty the nasopharynx, which is, at the same time, partly occluded below by the low placed velum palate. It is in such a nasopharynx that adenoids form, and complete the obstruction, so that only the mouth remains for breathing. It is therefore readily apparent that removal of adenoids is only a step in the direction of the restoration of natural respiration. In discussing the mechanism of this condition the author does not mention the relationship which is believed to subsist between high palate and deflected septum. For him the problem, because bound up in the development of the upper dental arch, is one for the oral surgeon, for dental orthopedics. This solution of the problem is not of recent origin—in fact, it goes back at least thirty years. The ordinary devices for spreading the upper jaw in the interest of proper alignment of the teeth also tend to overcome the high, steep palate.

Schlager's Functional Test of Renal Activity.—Wechselsmann refers to the intravenous injection of lactose for determining the efficiency of the glomerulous structure of the kidney, with incidental relation to the use of salvarsan. These lactose injections, however, have often been known to cause a violent reaction—chill, fever and vomiting—so that this superior diagnostic resource has been abandoned in some quarters in which the reaction incidence has been as high as 33½ per cent. In some clinics the intramuscular injection has been substituted. But these reactions can hardly be caused by chemically pure lactose. The commercial product such as has been used throughout often contains fungi and other impurities. The author has been testing his lactose for moulds by using special culture media (maltose agar) and makes use solely of sterile specimens in fresh ampoules. In time these become foul, even when pasteurized. The author finally succeeded in preparing ampoules of aqueous solutions of lactose which are guaranteed not to produce the slightest reaction. Of course this new product has become a proprietary under a trade name. The author has employed it for two and a half years and upon thousands of cases, yet never once has he seen any kind of reaction follow its use. Even in mercurial nephritis has he ever seen bad consequences. The diagnostic value of the lactose injections has been admitted by practically all clinicians who have used it. The author is connected with the Rudolf Virchow Hospital at Berlin, and several colleagues have testified as to the harmlessness of the ampoules. The latter are tested in all conditions in which there might be a renal lesion, and in salvarsan therapy the special indication is to determine first the soundness of the kidneys before injecting the antisyphilitic. It would seem that pure lactose solutions could be obtained without having to depend upon a proprietary article intended for private profit.

Münchener medizinische Wochenschrift.

January 18, 1916.

The Diagnostic Value of Gonococcus Vaccine.—Asch and Adler state that we need badly some test to assure us that the gonococcus is no longer in the system, after a period of intensive treatment with clearing up of symptoms. This need which was sufficiently pronounced before the war, has become doubly so in con-

nection with soldiers before returning them to the hardships of the front. One of the authors (Asch) has practised a diagnostic test for several years. In several hundred of the tests made upon troops, 100 gave positive results (42 acute and 58 chronic cases). The injection when possible was made under urethroscopic control and in any case a bacteriological test was made of the urinary centrifugate, urethral discharge, etc. The therapeutic vaccine injection is only from 1,000,000 to 25,000,000 cocci, but for diagnostic purposes from 50,000,000 to 100,000,000 are required. The intravenous method possesses no advantage over the ordinary hypodermic. As a rule the injections are continued several days after all cocci have disappeared from the urethral discharge. When a positive result is obtained we see in from two to three days a urethral discharge and flocculi in the urine and degenerate forms of gonococci, mostly extracellular. The same forms occur in ordinary cultures; and as ordinarily found in the urethral discharge have both diagnostic and prognostic significance. One of the provocative diagnostic injections may not be sufficient, so that a negative result should lead to 1 or 2 repetitions with increased dosage (even up to 125,000,000). This applies principally to chronic gonorrhea.

Surgical Treatment of Nephritis.—Wilk operated on four soldiers with chronic nephritis because of the extreme gravity of the disease and the failure to respond to medical measures. The men were young and presumably vigorous, and the origin of the disease was a mystery. The men blamed exposure and the author suggested that the food and alcoholic indulgence could have played a part. There was extreme anasarca along with ascites, with urine reduced to 1/3 normal. The presence of red cells in the sediment was sufficient to prove the existence of an inflammatory state. The author even proved the "medical" or bilateral nature of the nephritis by urethral examination. Both organs were equally compromised. Decapsulation was performed in all four cases. But one kidney was attacked, twice the right and twice the left. In each case the operation was successfully performed and successfully withstood. As the capsule was adherent externally, separation was tedious and difficult. The cortex was cyanotic, and in places there were large bullæ containing serum between it and the capsule. The kidneys were from two to three times their normal size, and the capsule had become so tense that they were lobulated. Nevertheless, the capsule readily peeled off, but with considerable escape of blood. Within a few days there was notable improvement in the disease picture. Hematuria, however, was present from the first, and calcium chloride was required to check it. In six weeks the anasarca had entirely vanished, and albumin was present in the urine only in traces. The author is in doubt as to the nosologic status of all of these cases. They may have originally represented a functional disturbance, secondary to inflammation of the pararenal tissue. Under such conditions we can very well understand why decapsulations so promptly relieved the renal disability. Apparently the relief effected in only one of the kidneys was sufficient to unburden the other.

The Medical Student and the War.—Charles M. Benson announces that the medical student will be of more service to the nation if he continues his studies and qualifies in three, four or five years' time than if he joins the army as a combatant at present. Also that the country requires, and will require, more doctors, but is getting, and will get, fewer.—*Medical Press and Circular.*

Book Reviews.

AN AUTOBIOGRAPHY. By EDWARD LIVINGSTON TRUDEAU, M.D. Illustrated. Price \$2.00. Philadelphia and New York: Lea and Febiger, 1916.

THE world of medicine owes much to the man whose life is here so modestly and so interestingly set forth, and not the least of its debt is on account of this book. Few men have accomplished so much, even without his handicap of ill health, yet what he did was only what another might do if he had the firm will and strong faith of Trudeau, and this book can but serve as an inspiration to many despondent youths who see, or seem to see, the frustration of all their plans and a ruined and shortened life before them. Trudeau's life was anything but what he had planned to make it, yet one can hardly doubt that it was richer in good accomplished, in happiness, and in fame than would have been the career he looked forward to in his early youth.

But this story of a noble life, so simply told, is not one of inspiration only; apart from the lessons it teaches, it is a tale of absorbing interest, richer in adventure, fuller of action, and more replete with genuine humor than many a work of fiction, and it is moreover a recountal of actual deeds, of the accomplishments of a real man. Even were it none of this, it would remain a priceless contribution to the history of medicine, an invaluable account of that campaign against tuberculosis in which Trudeau was one of the greatest generals.

CHIMIE PATHOLOGIQUE TROPICALE DE LA RÉGION ATLANTIQUE. Dr. G. DELGADO PALACIOS, Professeur à l'Université de Caracas, Venezuela. Membre de l'Académie de Médecine. Avec trois planches en couleurs. Caracas: Lit. y Tip. del Comercio, 1914.

WHILE the symptomatology, diagnosis, and treatment of tropical diseases have received a due amount of attention, the chemical pathology of the torrid zone has not as yet been very carefully studied. In the present volume numerous phases of this subject are considered, particularly those in relation to the intestinal flora and the absorption of decomposition products from this region. Several new varieties of intestinal bacteria are described, one, *Micrococcus oxycyanogenes*, which produces a blue substance termed oxycyanin, which is related to hemoglobin, and others which the author groups under the heading of leucochromogenic bacteria. These produce certain urinary pigments, cholerythrin, pseudoindirubin, pseudo-urobilin-B, etc., which replace the uroerythrin and urorosin of the temperate zone. The chromogens of these pigments in combination with calcium form a substance which appears in the feces, often in considerable amounts, in the shape of brownish granules which the author calls fecal "carcoma" or wood dust. Some of these substances, notably the chromogen of cholerythrin, may be deposited in the liver, spleen, kidney, and other organs, and their presence is associated by the author with the lesions of certain tropical diseases, especially yellow fever. They are also considered by him to be of interest in connection with the origin of diabetes, a disease characterized in the tropics by a lessened tendency to acidosis and coma. There is much of real interest in the book, and while of course the observations need confirmation, they are highly suggestive and deserve the consideration of workers in this field.

THE HEALTH-CARE OF THE GROWING CHILD. His Diet, Hygiene, Training, Development, and Prevention of Disease. By LOUIS FISCHER, M.D., Author of "The Health-Care of the Baby," "Infant Feeding in Health and Disease," "A Text-Book on Diseases of Infancy and Childhood"; Attending Physician in Charge of the Babies' Wards of Sydenham Hospital, and to the Willard Parker and Riverside Hospitals; Former Instructor in Diseases of Children at the New York Post-Graduate Medical School and Hospital, etc. Price \$1.25 net. New York and London: Funk & Wagnalls Company, 1915.

THIS book is designed to instruct the mother when remote from her physician, but like many books on popular medicine it attempts too much. For example, it is stated in the preface that the mother is shown how to recognize measles, chickenpox, and smallpox, although even the experienced physician may at times find some difficulty in making a positive diagnosis of any one of these diseases. Again, the frontispiece, which shows the appearance of the normal throat and the throat in tonsillitis, is decidedly an unsafe guide for the parent,

for inspection alone may leave the physician himself in doubt as to whether he is dealing with a case of follicular tonsillitis or one of follicular diphtheria. In spite of its shortcomings, however, this book has many good features, among which may be mentioned the descriptions and illustrations of exercises, and the succinct delineation of the common ailments of childhood. The subject matter is couched in language easily understood by the average parent, and the illustrations are generally good and helpful. The mechanical features of the book leave nothing to be desired.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. A new and complete dictionary of terms used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, Veterinary Science, Nursing, Biology, and Kindred Branches; with new and elaborate tables. Eighth Revised Edition. By W. A. NEWMAN DORLAND, M.D. Price, \$4.50 net; with thumb index, \$5.00 net. Philadelphia and London: W. B. Saunders Company, 1915.

THERE is little new to be said of a book which is in its eighth edition, for by this fact alone it has proved its right to existence, and final criticism, favorable or unfavorable, of the work as a whole has long since been passed upon it. In this edition one naturally finds a number of new terms—some of them, however, bearing witness to the reviser's zeal for all-inclusiveness rather than to his good judgment. For instance, one early meets the term *abman*, which is defined as "anything which is believed to act as a carrier for maneffluvium." This definition leaves one no wiser than before, for the compiler neglected to define maneffluvium. Words of this sort belong to the "abracadabra" class, useful in swelling the number of definitions but with no right to inclusion in a dictionary of medicine. The pronunciation of the French terms in this work is so bad as to be positively unneutral.

THE MEDICAL CLINICS OF CHICAGO. November, 1915. Published bi-monthly. Price, \$8.00 per year. Philadelphia and London: W. B. Saunders Company.

IN this number there are reports of eighteen cases from the clinics of eight men. One case of tuberculoma of the right cerebellar hemisphere receives well-merited and extended attention at the hands of both internist and ophthalmologist. A case of subacute Landry's paralysis is thoroughly discussed, but on the other hand some of the cases are presented in a very hasty fashion. The publication maintains the character with which it is started and necessarily some of its faults, but one must admit that, so far, each number has shown a certain amount of improvement over its predecessor.

"SPEAKING OF OPERATIONS," by IRVIN S. COBB. Illustrations by Tony Sarg. Price, 50 cents net. New York: George H. Doran Company, 1915.

A BRIEF, clever and very funny description of a man's experience with the medical, and surgical, profession, written exclusively from the layman's point of view. It will be found a reliable source of amusement to fill an idle moment.

POST-MORTEM EXAMINATIONS. By WILLIAM S. WADSWORTH, M.D., Coroner's Physician of Philadelphia. Price, \$6.00 net. Philadelphia and London: W. B. Saunders Company, 1915.

ONE of the most difficult and exhausting tasks which the pathologist has to perform is the making of a careful and thorough post-mortem examination. The greatest success in the application of knowledge and experience to the problems involved can be obtained only in those instances where the technical ability has been so developed that it has become automatic. The beginner in the post-mortem room finds that he is so busy with the technique of his problem that often important points slip past, and his report is defective to that extent. This book has been written to help the novice at the autopsy table, but the experienced pathologist will find in it much that is of value. The author describes in minute detail the process of making a complete post-mortem examination, telling what to look for and how to do it. In addition there are chapters on Special Conditions and on Medicolegal Post-mortems. The work is profusely illustrated with excellent photographs which really illustrate the point which it is desired to show. The author has a rather dogmatic attitude toward his subject, which is perhaps justified by his wide experience, but his views are generally sound, and his technique excellent. The book is one that should find a place in all pathological laboratories.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held February 3, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THIS meeting was held under the auspices of the Section of Medicine.

The Diagnosis of Pulmonary Tuberculosis, with Special Reference to Early Diagnosis.—Dr. LOUIS V. HAMMAN of Johns Hopkins Hospital, Baltimore, read this paper. He said that ten years ago, when the tuberculosis campaign was started, the cry was, "Tuberculosis is a preventable and curable disease." Indeed, stress was laid mainly upon its being a curable disease. It was assumed that every case of pulmonary tuberculosis had an early stage; that this stage could be diagnosed by the skilful; that early diagnoses assured recovery and therefore, that the solution of the tuberculosis problem depended in large measure upon the diagnostic skill of the medical profession. However, in spite of all their efforts, cases of incipient tuberculosis were almost as rare to-day as they were ten years ago. The question arose as to why the early stage of the disease so persistently eluded them. Did the cause reside in the apathy of patients who delayed presenting themselves for examination, or was the medical profession indifferent? Were the technical difficulties so exact that only a few could master them? Or, finally, did the course of the disease present obstacles that were well nigh insurmountable? Indifference to apparently trivial symptoms, and complacent faith in the healing virtue of time, often encouraged a physician to substitute a routine prescription and jovial reassurance for a thorough examination. Mistakes were due far more commonly to carelessness than to the difficulty of diagnostic methods. The undue emphasis that had been put on the physical examination, by distracting attention from other no less important factors, had rather obstructed than facilitated early diagnosis. The apathy of patients, the indifference of physicians, and the difficulties of methods of examination, partly explained the rarity of incipient tuberculosis, but they did not account for it fully. Pulmonary tuberculosis did not always begin in the insidious fashion that propagandists delighted to picture; quite as commonly it settled abruptly upon the victim, and at once involved such a large area of lung and produced such acute symptoms that the disease had no early stage. There was here no chance to display diagnostic skill, for one was totally ignorant of the subtle warnings, if such there were, that foretold the coming catastrophe. Nevertheless it was well known that such sudden outbursts were always preceded by infection, and that a focus of the disease must have been lying dormant in the lung or in a gland. Perhaps if more attention was paid to the discovery of the latent focus of infection one might by appropriate measures ward off these disastrous clinical manifestations. There was one difficulty in the way of early diagnosis of pulmonary tuberculosis that had no counterpart in any other infection and that was that in all other infectious diseases infection and disease were practically synonymous terms; but this was not so in tuberculosis, where the aim of diagnosis was a nice distinction between infection and disease. As was well known there was an almost universal infection of man by the tubercle bacillus, which acquired clinical importance only when it advanced far enough to give disturbing evidence of its presence. In tuberculosis the problem of early diagnosis was not to discover the first evidence of invasion by the bacillus, but to detect, if possible, the stage when latent infection threatened to pass into active disease. The portents of this stage were not at all easy to discern, and sometimes the transition was executed so rapidly that recognition defied the most alert skill. Finesse in percussion and auscultation did not carry one to the end of the diagnostic road; for the lungs of most adults and indeed of many children showed the scars of numerous lesions, and with the present methods of observation they were unable to determine at what time the injury was inflicted. Slight apical abnormalities, such as slight changes in the character of the percussion note and of the breath and voice sounds were evidence of infection and not of disease and taken alone did not decide the diagnosis. Apical râles, however, had a direct and unquestioned significance in the diagnosis of pulmonary tuberculosis. Definite moist râles at the apex when other clinical find-

ings pointed definitely to the presence of pulmonary tuberculosis practically assured the diagnosis. In making the physical examination it was important to have the patient cough that one might not miss the opportunity of detecting the one conclusive feature of the investigation. Pulmonary examinations were still one of the most difficult fields of internal medicine, and one had no right to expect unusual skill in the ordinary physician; and hence it was important to emphasize factors in diagnosis that were more readily determined, namely, the patient's story and the commonplace instruments, the thermometer and the scales. Hemoptysis was an initial symptom of invasion in nearly ten per cent. of the patients with pulmonary tuberculosis. If the significance of this one symptom were conscientiously regarded it would be a great boon to early diagnosis. There was but one absolutely indisputable evidence of pulmonary tuberculosis, namely, the appearance of tubercle bacilli in the sputum. Unfortunately, this was but rarely a sign of early involvement. Nevertheless, it seemed to the writer that in their eagerness to detect the very first stage of the disease they had somewhat neglected the value of sputum examinations. He had the impression that the sputum was not as carefully and conscientiously searched as it was fifteen or twenty years ago when it played a more important rôle in diagnosis. Even the simple microscopic inspection of sputum had an important diagnostic bearing since a hurried glance usually sufficed to distinguish true pulmonary secretion from the mucoid discharge raised from the nose and throat. Sputum examinations to have value should be performed frequently, if there must be a choice, frequently in the usual simple way, rather than occasionally by the more complicated methods. The Roentgen ray which had done so much to assist them in the correct interpretation of gross pulmonary lesions, had proved of little help in the diagnosis of early pulmonary tuberculosis. The Roentgen ray portrayed slight pulmonary changes, but the clinical interpretation was uncertain, because the Roentgen ray could give no etiological or physiological information that would enable one to distinguish between an active or inactive lesion. In this respect the Roentgen ray had all the shortcomings inherent in a physical examination. The writer then discussed the various immunity reactions and stated that tuberculin would never draw a sharp line between infection and disease, and they had no right to expect it to make this distinction. The subcutaneous test was the most certainly eliminating test, for if a patient failed to react to ten or even to five milligrams of old tuberculin one might feel assured that he had no active early lesion. The intracutaneous test, if performed with appropriate dilutions of tuberculin, had a value almost equal to the subcutaneous test in eliminating tuberculosis. Of somewhat less value was the cutaneous test. For lesions open to inspection a focal reaction at once decided the diagnosis. In the use of the tuberculin tests a high degree of hypersensitiveness spoke for activity; a low for quiescence, but there were many exceptions and wide overlapping, so that great caution must be observed in drawing clinical inference. The early diagnosis of tuberculosis was nearly always a probability diagnosis and the lesson for the physician was that he must act upon reasonable probability and not allow the patient's life to be thrown away as he calmly waited the full verification of his suspicions. The important lesson for the sociologist was that he must see the insuperable difficulties in the way of early diagnosis on a large scale and abandon his efforts to make early diagnosis an essential feature of the campaign for the eradication of tuberculosis.

The Diagnosis of Genitourinary Tuberculosis.—Dr. JOHN W. CHURCHMAN of New Haven, Conn., read this paper (see page 511).

Therapy as Related to the Immunology of Tuberculosis.—Dr. EDWARD R. BALDWIN of Saranac Lake, N. Y., said that the knowledge of immunity processes in tuberculosis had not been applied sufficiently in judging therapeutic methods. The tubercle itself was an expression of resistance and any medication that acts on the tuberculous tissue was capable of good or ill effects. The inflammation which accompanied a new outbreak of tuberculosis appeared to destroy many bacilli, and from the intermittent reactions induced in lupus by various means, healing and absorption occurred. Heliotherapy, artificial light, the x-ray, and radium induced reactions in the tubercles similar to tuberculin. Some of the recent chemotherapeutic methods, such as the use of gold cyanide and boric acid-cholin, were supposed to

have a direct influence on the tubercle bacilli, but might act only indirectly, the favorable influence being due to the focal reactions. These reactions are more dangerous in pulmonary than in surgical tuberculosis. No special affinity for tuberculous tissue had been found in iodine, arsenic or copper. There was no satisfactory method as yet of measuring immunity to tuberculosis, but serum reactions and tuberculin skin tests should be studied in conjunction with new medication.

Dr. HERMANN M. BIGGS, New York State Commissioner of Health, said that Dr. Hamman had spoken of the campaign in the study of tuberculosis during the last ten years, and he thought it was unfortunate to have the impression exist that this campaign had extended only over this period of time, because it had existed much longer, both the scientific study and the practical preventive measures that had been introduced by it. In New York City this campaign practically began in 1893, more than twenty years ago. Dr. Biggs said he did not find himself in agreement with Dr. Hamman when he said that no more cases of incipient tuberculosis were recognized now than earlier, for that was at variance with the feeling that most of us had. At Otisville this was not borne out unless one defined the term incipient tuberculosis more strictly than was customary. When he was in charge at Otisville 40 per cent. of the patients did not have the tubercle bacilli in the sputum either at the time of admission or during the time of treatment. A large percentage did not have any considerable amount of disease. Recently he had asked for an opinion from those who worked on tuberculosis as to what had been done and what had been accomplished during the last eight years, that was since the last International Congress on Tuberculosis, and at least three referred to the fact that now the diagnosis of tuberculosis was too often made and when it was not justified. Dr. E. R. Baldwin had written: "In the eagerness to make an early diagnosis of tuberculosis, injustice has been done to some persons by placing the stigma on those who at the worst are only suspected cases. A greater feeling of responsibility is needed by medical men engaged in tuberculosis work and especially by the examiners for public institutions." Dr. James Alexander Miller had written: "Another important feature in my opinion is a more strictly medical problem. It appears to me that we are noting a reaction from our former frequent medical mistakes because of which many cases of fairly marked tuberculosis were overlooked. At the present time I feel that in our eagerness to make early diagnoses many physicians are erring on the other side and that consequently our standards for the early diagnosis of tuberculosis may need revision. If I am correct in this opinion, there are a great many individuals to whom a great injustice is done by having a positive diagnosis of tuberculosis made when the most that is justified is a diagnosis of an old inactive disease." Of course this was a difficult problem. It was not simply a question of tuberculosis being present, but what they really wished to know was whether the lesion was active; was there an active disease present? It seemed to him that the onset which was regarded as the beginning was acute frequently enough; the onset might be as acute as the acute disease. But in a large per cent. of the cases, if they went back carefully in the history, they would find a period of weeks or months in which there were evidences of failing health. Many cases with an acute onset were really not followed by extensive disease. They might have hemorrhages, or pleurisy with effusion, after the acute symptoms had cleared up, but there might be a great deal of inflammatory reaction with acute infection and extension that in large part cleared up. After a few weeks they would find the real tuberculous lesion not so extensive. Therefore, he said he would take exception to Dr. Hamman's statement that the socialists must give up hope of preventing tuberculosis except when an early diagnosis was made. Perhaps too much emphasis had been placed upon early diagnosis. It did not seem to matter what was done in the way of prevention. The English stated that they took this position, that it was not necessary to remove the case from the community because the people were all infected anyway. Whether they were infected a little more or less did not matter. It was a question of environment alone that should be considered. It was a disadvantage to remove these patients even when they had positive sputum. Wright stated that to remove all these people from a community would raise the fear that the remaining ones would become more susceptible, a decided disadvantage. Therefore, they treated the

cases among the poorer classes in London in their homes. Dr. Biggs said he had no sympathy with this attitude. People should be treated in accordance with common sense rules and scientific thought. Most of the cases occurring in infants either died or got well before adolescence. Then came greater exposure, greater susceptibility of the pulmonary tissues, and then the disease was a different infection from that which occurred in infancy. Dr. Biggs had no doubt but that the preventive measures being now adopted were most efficient in the actual prevention of the disease.

Dr. HAVEN EMERSON, Commissioner of Health of New York City, said that the figures now available showed that only those patients were sent to Otisville or other institutions who had a positive sputum. And so one might consider the discussion which might take place ten years from now reasoning from the status of the patients at Otisville; then they might not forget the definite changes that had taken place in the sanitary control of the disease at certain periods. Patients with positive sputum should be removed because they might become a menace to their neighbors. At Ray Brook it was formerly difficult to get the early cases; the inmates were in the second and third class of cases. The physicians in New York City were then apparently unable to make the early diagnoses. To-day, however, there was a waiting list at all times of incipient and active cases. This was an evidence of a progressive acuteness on the part of the profession in making a diagnosis of these cases. The specimens of sputum sent to the Department of Health for analysis showed an increasing number that were not positive, and this showed an early alertness on the part of the physicians. They must come to the conclusion that the social control of tuberculosis was possible. Dr. Emerson presented some figures for the year 1915 which were of interest in the social grouping of these patients. If we took 100,000 people on the East Side in the Jewish district, the general death rate was 11.3; that from tuberculosis was 1.11. If we moved over to the colored region with its population of 75,000, the general death rate would be found to be 20.9, that from tuberculosis 3.3. If we went to the upper West Side along Riverside Drive the general death rate would be found to be 13.6, that from tuberculosis 0.8. There we had a difference in similar communities, so far as numbers went, from tuberculosis which varied from 0.8 to 3.3, one community having four times the death rate of another. Among the Irish and Jews the tuberculosis death rate was 3.2. To effect the greatest relief to these sufferers they should have medical supervision; the relief would be greater and more continuous if they depended upon medical standards and not on economic standards.

Dr. WALTON MARTIN discussed the surgical aspect of these cases and said that in the first place in surgical tuberculosis we should consider how the focus of infection originated in the body. In all cases of tuberculosis of the bones one must consider the blood stream infection. It was surprising that the orthopedic surgeon obtained such excellent results by simply giving the parts rest, even without further treatment. In any case, after removing the main focus, the patient should be placed in favorable surroundings, at least for a short time. He called attention to the multiplicity of lesions that one occasionally saw and referred to a man with tuberculosis of the ankle and then tuberculosis of the rib. He went away for six months and returned with tuberculosis of the testicle. He again went away for six months, lived in unfavorable surroundings, and returned with tuberculosis of the seminal vesicles. They were removed and now he was practically well and at his job as a ticket-chopper.

Dr. ALFRED MEYER said that he had had experience with extensive bone lesions and his suspicion was excited that these extensive bone lesions were of bovine origin and he asked that those who had the opportunity of studying cases of bone tuberculosis, not involving the lung, would enlist their aid to help determine if these cases were bovine and not human tuberculosis. Recently Dr. Meyer had learned that in the public schools the examinations were made with the clothing on and he asked how one could reach any conclusions regarding the existence of incipient or advanced tuberculosis if such examinations were made through the clothing. That was to him a faithless method of procedure. It was not due to the ignorance on the part of his colleagues but indifference. It really took three-quarters of an hour to make a proper examination of the human chest, and that meant the stripped chest. Personally he admitted that he gave every person he examined at

least twenty minutes before he attempted to reach an intelligent conclusion. He advised against using auscultation before percussion. All students should be taught the method of continuous percussion, especially if they were trying to ascertain whether the base of the lung was thoroughly aerated. There was a series, a composite picture as it were, produced as the individual took a long breath and let it out again. With regard to inspection, this should be done both in front and behind. The whispered voice was a valuable diagnostic aid. In a general survey of the situation he agreed with Dr. Biggs that an early and careful diagnosis was more frequently made nowadays than it was fifteen or twenty years ago. The pendulum had swung the other way. Dr. Meyer referred to scoliosis occurring in working girls. Pictures of them were spread about for educational purposes. These individuals would lose their sleep, lose their appetites, etc., and they would come to the physician looking the very picture of those afflicted with tuberculosis but without any tubercle bacilli being found. He excluded slight cases of scoliosis. He said that if they would be made to stand straight, with their hands by their sides, and if they were watched carefully, the proper diagnosis would be made.

Dr. JAMES A. MILLER said he was much impressed with two or three matters that occurred to him. In Dr. Hamman's paper he said he was much impressed with the emphasis placed upon the importance of diagnosis and symptomatology. Too much emphasis had been placed upon slight abnormalities of physical signs, he thought. In many of these patients certain obscure signs would all clear up in a short time. He could not agree with Dr. Hamman regarding what he said about making an early diagnosis; the fact was that we rarely saw these individuals in the early stages of the disease. In dispensaries and other institutions in New York last year there were 34,000 cases, and nearly one-half were new cases. Of these 30 per cent. were discharged, after adequate study had been made covering a period of months, with a diagnosis made of other conditions than tuberculosis. Dr. Miller thought there was too much refinement of classification and of what was meant by the symptoms. It did not make any difference whether or not the case was a classical one; give the patient the proper treatment. When the disease was localized, and not far advanced, the sanatorium was the place for these patients. If one compared the dispensaries of to-day with the dispensaries of years ago, he would note that we seldom saw the large numbers of bad cases now that we did then. That in itself was good evidence that we were making some progress; although we might have as many cases, the type of cases differed. With regard to the use of the *x*-ray he agreed that while it was often difficult or impossible to make a diagnosis of early tuberculosis by this method, it might be of value in cases in which there was thought to be a moderate amount of disease as shown by the physical signs. One, too, was often surprised that the *x*-ray showed a great deal regarding not only the extent of the disease but also its character. It gave additional important information as to what was going on in the chest. If the diagnosis was difficult to make in the early stages of the disease in adults, it was more so in children. We all had a feeling that there was a great deal of tuberculosis in children, the early recognition and proper care of which would have a great effect upon the future. Again, we should remember there were a great many non-tuberculous patients that required the same care as the tuberculosis. In spite of what Dr. Hamman had told us in his splendid résumé and of the specific therapy spoken of by Dr. Baldwin, Dr. Miller said, after all the situation was rather pessimistic. One prominent physician had told him that "it did not make much difference about the stage of the disease; at the end they all died." He thought we ought nevertheless to look to the future with hope and with confidence. Much had been done and much was being done to-day in the education of the public. Getting these cases early was most important, and the people should be educated how to recognize suspicious symptoms; they then could come to the physician in the early stages and when the disease offered the best hopes for cure. As to the prevention of tuberculosis in children, with or without the disease or the predisposition to the disease, we ought not to be discouraged.

Dr. HAMMAN closed the discussion. He said he had been misunderstood for he did not mean to say that nothing had been accomplished by the antituberculosis

campaign. This campaign got a fresh start ten or twelve years ago. With regards to the early diagnosis of incipient tuberculosis he wanted his audience to understand what he meant by "incipient tuberculosis"; his definition was that of the International Association on Tuberculosis. With such a definition in mind every incipient case of tuberculosis could be diagnosed with absolute certainty. There were two groups of cases, those with tubercle bacilli and those without tubercle bacilli, and it was largely a matter of personal opinion on the part of the physician who first examined these cases as to whether they required sanatorium care or not. This broad measure of prevention was very expensive; it certainly was very expensive to treat say 100 persons when only five or ten of that number had definite clinical tuberculosis. The main point Dr. Hamman wished to emphasize was that the treatment of pulmonary tuberculosis from the broad standpoint of prevention had been a failure. He did not mean to say that patients with tuberculosis did not get well, but his experience had been that patients with tubercle bacilli in the sputum and who were sent to the sanatoria, improved; but when they were sent back to the city, after five or six months in the city, they would break down again and be sent to institutions where the advanced cases were received.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 23, 1915.

DR. LEROY BROWN IN THE CHAIR.

Presentation of Specimens.—Dr. HERMANN J. BOLDT presented the following specimens:

1. **Fibroma of the Left Ovary Showing a Distinct Capsule.**—This might be considered unusual inasmuch as such ovarian tumors merged into an indistinct tumor which destroyed all evidence of ovarian tissue. Quite frequently microscopical examination showed a malignant change, or they might be of malignant character primarily. In this instance this was a pure fibromatous condition only. The patient from whom the tumor was removed was 27 years of age and her only symptoms were a heavy sensation in the left iliac fossa and pain of moderate severity upon physical exertion.

2. **Ovarian Cyst Showing Well the Ovarian Attachment and the Line of Excision.**—This method of conservation should be practised whenever feasible in non-malignant ovarian tumors.

3. **Adenocystoma of Large Size on One Side with Tuboovarian Cyst on the Other Side.**—Although the tuboovarian cyst was of small size it was not feasible to do conservative surgery since no vestige of normal ovarian stroma was evident. The only symptoms in this case were increased size of the abdomen and hardness in the region of the enlargement.

4. **Fibromyomatous Uterus Removed by Abdominal Hysterectomy after Six Exposures to X-Ray Treatment Had Failed to Diminish the Profuse Bleeding.**—The patient from whom this specimen was removed had had profuse menstruation for five years and during the last year before operation had lost large quantities of blood for ten days to two weeks. The *x*-ray treatment gave entirely negative results.

5. **Septic Uterus Removed by Abdominal Hysterectomy.**—This patient had been delivered by version, and upon the development of symptoms of sepsis had been curetted. Two days after the curettage Dr. Boldt said he saw the patient in consultation. The microscopical examination showed the microorganisms had invaded the myometrium nearly to the serosa. Curettage could not be too severely condemned in such cases. Death followed the operation on the second day.

6. **Myomatous Uterus Removed by Vaginal Hysterectomy.**—This patient had menorrhoea and metrorrhagia that could not be controlled by non-surgical measures. As she was 47 years of age vaginal extirpation of the myomatous uterus was deemed preferable.

7. **Carcinoma of the Cervix Showing Distinct Line of Demarcation.**—The specimen showed invasion of the lower segment of the corpus, thus demonstrating the fallacy of high amputation of the cervix. The specimen also showed the impossibility of determining the primary seat of the disease.

8. **Adenocarcinoma of the Body of the Uterus.**—This specimen showed that type of adenocarcinoma that affects the endometrium without extending deeply into the myometrium.

Dr. ARTHUR STEIN said that in looking over the liter-

ature in reference to the treatment of myoma of the uterus with the x-ray he had found quite a number of cases in which x-ray treatment had been employed and in which operation eventually had to be performed. In all these cases malignant degeneration was found. He was at present preparing a paper warning against the use of the x-ray in the treatment of myoma cases. On the other hand, the x-ray had a large field of usefulness in the treatment of hemorrhage at the beginning of menopause where the possibility of malignant degeneration could be excluded by the use of the curette. When these cases were treated by the x-ray one usually saw a quick stoppage of menorrhagia.

Dr. LEROY BROWN said that with reference to the case in which Dr. Boldt had removed the cyst wall and left as much of the ovary as was possible, if the tumors were small he approved of the course that was taken, but if the tumor was large he did not feel inclined to act in the same way, since large tumors were more likely to be papillomatous than were small ones. Dr. Brown said that of late years he had gone back to the old method of using a large aspirating needle and withdrawing the fluid from the cyst, thus reducing the size of the tumor. One could evacuate a tumor in this way so that when the needle was withdrawn not a single drop of fluid escaped. Dr. Brown asked Dr. Boldt if there was anything suggestive of pure fibroma in this case.

Dr. BOLDT replied that a section taken from the center of the capsule showed it to be a pure fibroma.

Dr. BROWN said that as to the use of the x-ray in cases of hemorrhage, he felt that this was a sheet anchor in the relief of these hemorrhages. In carcinoma of the cervix Dr. Brown said that twenty years ago he had a feeling that the treatment then employed was a thing of the past and that they should do either a hysterectomy or some form of cauterization. He wished that Dr. Boldt had given them the final results of the operations in the cases of carcinoma of the body of the uterus, because in looking over the records of the Woman's Hospital (but not the final records) he found that of the patients presenting themselves for operation for cervical conditions, about one-fourth of them had carcinoma of the cervix, which could apparently be permanently cured. In his experience about one-half of the cases with carcinoma of the body of the uterus could be placed as possibly permanently cured. The final outcome in these cases unfortunately had not been traced.

Dr. BOLDT, in closing the discussion, said that as to the conservative treatment of ovarian tumors, he felt that the need of surgery depended upon the actual conditions present. The specimen of ovarian cyst which he presented was not a small one and he thought it would have been bad surgery to have taken the ovary out; it was better in these cases to do conservative surgery. As to diminishing the size of a tumor by use of a trocar, his experience had shown undesirable results, and he had come to the conclusion that a large abdominal incision was better surgery. With reference to myomatous uteri he thought that if the ordinary means of treatment failed it was better to subject the patient to extirpation of the myomatous uterus and that it was not desirable to try the x-ray treatment. A study of the results of high amputation of the cervix for cancer of the cervix showed that the results were as good as with vaginal hysterectomy which was done in former years. He had been impressed by the fact that adenocarcinoma of the body of the uterus if not far advanced showed not less than 50 per cent. of permanent cures. As to the cases of septic uterus it was better to treat these in a conservative manner, by leaving them alone.

A Peculiar Case of Intraabdominal Abscess.—Dr. HENRY DAWSON FURNISS reported this case, which occurred in a woman, 40 years of age, who came into his service at the Post-Graduate Hospital in September of this year. The patient stated that she had two children and two miscarriages, the last induced. At the time of admission to the hospital she stated that she had missed two periods and that a midwife had attempted to induce abortion but that no fetus or large clots of blood had escaped. The midwife made a second attempt and again the result was only slight bleeding from the uterus. The patient's temperature at the time of admission was 100° F. and her pulse 90. Examination yielded no evidence of attempts at abortion. In the region of the left tube there was a slight tenderness but nothing could be felt. For three days her temperature remained about the same; then it went to 102°

and the pulse to 115. At this time she complained of pain in the lower left abdominal region. The leucocyte count was 15,000 with 80 per cent. polymorphonuclears. Further examination showed a mass about the size of a hen's egg in the lower left portion of the abdomen, superficial and more anterior than one would expect with a pus tube. At operation the omentum was found adherent to the abdominal wall on the left side. In breaking this loose an abscess containing about two ounces of pus was evacuated. There was no evidence of any involvement of the tube or ovary. The patient made a slow but uneventful recovery. It was later learned that the patient had been using morphine and had given herself a number of injections into the abdominal wall. This had caused three or four areas of induration. Possibly the abscess was produced by an injection into the peritoneal cavity. Dr. Furniss said that in looking over this history he was inclined to believe that the amenorrhea was due to morphine habituation and not to pregnancy.

A Case of Relaxed Vesical Sphincter with Incontinence of Urine Cured by the Kelly Operation.—Dr. HENRY DAWSON FURNISS reported this case, which occurred in a woman 41 years of age, who at her last confinement had a post-partum hemorrhage and was torn. Since this time she had had feelings as though the uterus was prolapsed. Three years ago she noticed that when she was walking she had some incontinence of urine. Later she became unable to retain her urine when on her feet. A year ago she noticed a hard nodular swelling in the lower part of the abdomen. Physical examination showed a first degree laceration of the perineum, the cervix lacerated and somewhat enlarged, the mass in the abdomen a pedunculated fibroid of the fundus of the uterus. After cystoscopy the patient, upon withdrawal of the instrument it was noticed that the sphincter did not close over the urethra as it should. An operation was performed at which the pedunculated fibroid was removed and a Kelly operation for the urinary incontinence was done. This consisted in making a median incision from near the urethral orifice backward to the cervix. The bladder was separated from the vagina about one and one-quarter inches on either side. A Pozzi catheter was placed in the bladder and as an attempt was made to withdraw this it localized the sphincter of the bladder. Mattress sutures were so placed that they infolded the urethral sphincter on its under surface as they retracted the sphincter. Two rows of three sutures each of linen were placed under. The wound was closed with catgut. While the patient was in bed for twelve days she had to be catheterized. At present there was no leakage and the patient could hold her urine three hours or longer.

Dr. HERMANN J. BOLDT, speaking of the Kelly operation, said that sometimes it failed entirely, sometimes the results showed some improvement, and sometimes they were good. This could, however, be said of all operations. The operation was one that struck him theoretically as being the best operation, and he thought that he would continue to use it. As to the case of abscess between the omentum and parietal peritoneum he had had one instance, but he had not been able to learn just what the cause was; the pus showed the presence of the colon bacilli which caused suppuration. It was likely that a local inflammatory area was infected by the colon bacilli.

Dr. HIRAM N. VINEBERG said that local infection in such cases as Dr. Furniss had reported occurred when an instrument perforated the uterus. He recalled the case of a woman admitted to the hospital with the omentum in the vagina as the result of an attempt to empty the uterus with some sharp instrument. She had only a slight temperature and made a good recovery. The omentum was excised, the rent in the uterus repaired, and an uneventful recovery followed. As to the operation of choice for incontinence of urine, Kelly's operation gave the best results, but even that failed quite frequently.

Dr. LEROY BROWN said that cases of incontinence of urine due to relaxed vesical sphincter were improved for a time only by operation. Dr. Boldt had described an operation before the American Gynecological Society which he had been using and in each instance the results had been satisfactory. In his opinion this was a thoroughly scientific surgical operation.

Dr. FURNISS said that in the case of the abscess the omentum was not adherent to the uterus. It was well against the abdominal wall and free in the abdominal cavity. In the cases of incontinence he thought one should always take into consideration the amount of

nerve damage that was done. In some the innervation was so damaged that no operation could be successful. Care should also be taken not to tighten the sphincter too much, thus causing a condition analogous to stricture and which might result in serious renal damage.

Uterus Bicornis Unicollis; Abscess in Right Cornu; Amputation; Normal Pregnancy in Left Cornu.—Dr. HARRY ARRANOW reported this case, which had been referred to him for a profuse, purulent, intractable leucorrhea by Dr. William H. Boese. The patient was 27 years of age and gave a history of very irregular menstruation, every five to ten weeks, of five days' duration, profuse and painful at times. She had been operated on at the Presbyterian Hospital for the condition for which she was referred to the speaker. Physical examination showed the os uteri discharging purulent material through an apparently normal os. There were apparently two uterine bodies, freely movable with deep depression between them. There was some fullness and tenderness in the right fornix. Pressure on the right side produced a free flow of pus from the cervix. The patient was admitted to the hospital with the diagnosis of uterus bicornis unicollis. At operation this condition was found. The two horns were of about equal size and development. The right cornu was amputated and the opening at the junction of the two cornua was closed with chromic catgut. The patient improved but still had some discharge. She was again anesthetized and after dilating the cervix she was curetted and the remains of the canal of the right cornu which had been left in the cervix was cauterized. The patient made an uneventful recovery. She shortly afterward married and became pregnant within a few months and was delivered of a normal baby at full term in September, 1914.

Abortion with Expulsion of the Placenta at the Third Month—Full-Term Baby at Nine Months (Probable Twin Pregnancy).—Dr. HARRY ARRANOW reported this case. He was called to see the patient when she was three months pregnant. She was suffering with severe abdominal cramps and profuse uterine hemorrhage. The cervix was soft and the os patulous. A piece of the placenta could be felt presenting at the os. Curettage was offered but refused. The cervix and vagina were packed and in the course of two days two pieces of placenta were removed, the patient ceased to bleed, and the case was dismissed. Four months later the patient returned, showing all the signs of advanced pregnancy. She was delivered of a normal baby on July 5, 1912, six months after the abortion.

Unusual Case of Ruptured Ectopic Pregnancy.—Dr. HARRY ARRANOW reported this case, which occurred in a woman 31 years of age. In the early part of July, 1915, realizing that she was pregnant, she made several attempts at abortion but without success. On August 5 she was seized with sharp pains in the right side and lower abdomen. She went into collapse and was rushed to the Lebanon Hospital and admitted to the service of Dr. Rongy. She presented all the symptoms of a ruptured ectopic pregnancy. There was one thing that did not fit with a diagnosis of ectopic pregnancy, and that was that the uterus was the size of a two months' pregnancy. On opening the abdomen the tubes were both found to be normal. On lifting the uterus a ragged hole was found on the posterior surface of the uterus about three cm. from the right border. The diameter of the opening was about two cm. The immediate supposition was that in the attempt to produce abortion the uterus had been perforated. However, on removing the clots of blood an ovum of about six weeks' development was found lying free in the pelvis. The abdomen was closed in the usual manner and the patient made an uneventful recovery.

Dr. JOHN O. POLAK asked if the case reported was not one of a uterus unicornis with a rudimentary right horn. Unless this was so he felt that the uterine wall was weakened by the extensive resection. He referred to a case in which the woman miscarried at three months but, notwithstanding, the uterus grew larger until it corresponded to full term size, when she had her labor and was delivered of twins, one a well developed child and the other a fetus papyraceous, flattened on the living companion. A large placenta showed the cord single.

Dr. HIRAM M. VINEBERG recalled a case in which a woman had an intraperitoneal hemorrhage and the abdomen was filled with blood. He pulled up one tube and found it perfectly normal; likewise the other. He then thought it would be better to deliver the uterus, and just behind the insertion of the tube he found a small

mass the size of an almond which caused the hemorrhage. Another case also came to his mind in which the surgeon opened the abdomen and finding it full of blood suspected the tubes. Finding nothing he closed the abdomen. The patient died, and at autopsy it was found that she had an interstitial pregnancy.

The Ultraviolet Rays in Gynecology; A Preliminary Report.—Dr. ALFRED HELLMAN read this paper in which he stated that the value of light therapy though possibly not proven from what might be called the laboratory or scientific standpoint had been shown empirically to be of undoubted value by the work of such men as Rollier at Leysin, and Bernhard at Smaden. The value of the particular rays at the ultraviolet end of the spectrum had likewise been shown. It had been proven that light was a bactericide and penetrated the human and other animal tissues. In many pathological conditions the value of the ultraviolet rays had been shown to be of value as, for instance, in many skin diseases, almost all forms of tuberculosis, wounds, gangrene, sciatica, neuralgia, anemia, chlorosis, leukemia, asthma, arteriosclerosis, gout, rheumatism, and of most interest to gynecologists in ulcers of prolapsed uteri, gonorrhea, menorrhagia, dysmenorrhea, fluor albus, and pelvic inflammations. The field of gynecological conditions to which ultraviolet and other light therapy might be applicable had as yet been very little explored. It was not even mentioned in the textbooks; even those on medical gynecology failed to speak of it. The reader of the paper said the work of Fromme of Berlin, the results of which he had personally witnessed, had stimulated his interest in this subject. In a paper read before the Gynecological Society of Berlin in 1914, and which had not to his knowledge been published, Fromme stated that sunlight therapy derived its great value from the fact that sunlight was rich in ultraviolet rays. These rays were rapidly absorbed and their action was chemical, bactericidal and physical (hyperemic). The local action was manifested by reddening of the skin, lasting three or four days and followed by a gradually darkening or brown pigmentation. Fromme reported 26 cases treated for pelvic inflammation, of which 25 were cured. The other was operated upon and proved to be an ovarian cyst. Dr. Hellman said that the method which he used was based on what he had learned from Professor Fromme at the Charité in Berlin. The apparatus used was the Küntzliche Hohensohn Lampe designed by Dr. Bach and Dr. Nagelschmidt. The burner was a transparent quartz tube eight to twelve cm. in length, on the ends of which were two transverse tubes which contained the mercury electrodes. The electrode vessels were provided with fan-shaped metal coolers with which the heat loss and the current consumption were regulated. On each electrode between the coolers was situated the beaded lead which conducted the current to the lamp. The lamp was suspended in a casing of highly polished aluminum. The upper hemisphere was the casing proper, while the lower half formed a closing cap. This cap was adjustable and had an aperture with a revolving screen behind it. This revolving screen had smaller apertures so that any desired amount of light could be allowed to pass. The entire lamp could be easily raised or lowered on an easily movable upright and tripod. A direct current was enclosed in a perforated nickel-plated casing and suspended from the upright. The resistance was especially constructed to meet the particular demands of the quartz lamp. Mounted on all of this was the switch and the plug to which the lamp was connected. The ultraviolet rays of the lamp which produced the therapeutic results were not at all absorbed by the quartz glass. The patient was placed before the lamp in a reclining position and the part of the body to be rayed was exposed. The eyes of the patient and of any one else in the room were carefully shielded by dark glasses. The lamp was then placed at the desired distance so that the ray fell where needed and the current was allowed to flow. The length of exposure was guided by a schedule suggested by Professor Fromme, always remembering that a brunette could stand in the earlier treatment a longer exposure than a blonde. At the first treatment the patient was placed 75 cm. from the lamp and the exposure was for one and one-half minutes. The second treatment was given on the third day, when the distance was 65 cm. and the exposure two and one-half minutes. Treatments were then given three times a week and the distance gradually lessened until the patient was 40 cm. from the lamp, while the time of exposure was gradually lengthened to twenty minutes. The reader stated that to date he could report eight cases of pelvic inflammation abso-

lately cured by this method. They were treated ambulatory without any other therapeutic measures being employed, and the diagnosis in each instance was confirmed by three colleagues. After relating the history of these eight cases the reader concluded that this method should be tried in every case of pelvic inflammation of the subacute and chronic variety before operation was advised, and especially if the more generally used methods had been tried.

Dr. JOHN O. POLAK said that Dr. Hellman's paper brought up a new field for gynecological consideration. In the first place one might ask what constituted a cure. They all knew that a large number of inflammatory conditions did clear up and disappear entirely if sufficient time was allowed, even when no violet rays were employed. In both post partum and post abortal infections the condition was often stimulated by manipulation. Many of these patients went from one doctor to another and from one dispensary to another and the condition was kept up by the repeated tamponing and manipulations. With the entire absence of treatment many of these conditions would clear up of themselves. The two points to be emphasized were that the pelvic organs should be left alone and that light and heat should be used as Dr. Hellman had done. Too much importance should not be given to the effect of light in these cases until they knew more about it.

Dr. HERMANN J. BOLDT said that the paper had brought up a new line of thought. He hardly felt that they were justified in accepting what had been said about the merits of the ultraviolet rays at the present time without further experience. As had been said, a large number of these cases if left alone would clear up and do nicely.

Dr. SAMUEL W. BANDLER said that during the reading of the paper the question that suggested itself to him was: "Was any other treatment given during the application of the ultraviolet rays?"

Dr. HELLMAN replied that the patients were told to rest as much as possible.

Dr. BANDLER said that he did not doubt that the therapeutic measure offered was of value but that Nature did more for these patients than anything that they could do. Conservative treatment of any sort helped nature. The giving of light and the ultraviolet rays only helped nature. The cure of pelvic inflammation of a chronic nature was accomplished in much the same way as was that of tuberculosis. An obstacle to improvement in these cases was that they were over-treated as a rule. Many of these patients did better if they were not treated at all. If manipulations of a forceful character were attempted it was natural that the inflammation, if mild or sub-acute, would not improve. This method presented by Dr. Hellman was valuable because it implied the absence of any local therapy which might irritate. It was quite possible that in the violet rays themselves there was something which stimulated the circulation and in that way enabled the patient to overcome and pass off the residual lymphatic irritation.

Dr. LE ROY BROWN said he could not fall in line with those who had entered into the discussion when it was implied that all treatment of pelvic inflammation had been done away with. Constant manipulation did not result in anything but disadvantage in such conditions, but there was no doubt that the old treatment was in assistance in placing these patients in a more comfortable condition. The employment of local applications at proper intervals was no doubt all right and he did not feel disposed to disregard this entirely. When the properties of the actinic rays were first brought to their attention it was shown that they were of sufficient strength to pass through the entire body. If this was possible it seemed to him that they might be of help in these acute processes that were deeply seated.

Dr. HIRAM VINEBERG said the discussion he had just listened to made him feel that they were all very poor observers. Otherwise how could it be that a therapeutic measure, which experienced men had advocated very strongly, would later be just as strongly condemned? To-night it had been stated that it was very dangerous to employ any local treatment in pelvic exudates, yet he could remember with what enthusiasm Brandt's pelvic massage had been adopted in pelvic exudates, and to his mind it was still a valuable procedure in chronic cases without any fever. One should be very modest in his claims with any therapeutic measure when the diagnosis and results depended upon pelvic and abdominal palpation. However, any therapeutic measure which promised any aid in the treatment of pelvic

ailments in women should be heartily welcomed. Whether the deep violet rays had such power had still to be proven, but from what he had learned of the agent in the hands of others he had grave doubts on that point.

Dr. HELLMAN, in closing the discussion, said there was absolutely no heat at all connected with this treatment and none of the results of heat were produced. He had tried to be as conservative as possible in the care of these patients and in his deductions. In the acute conditions he believed it would have been suicidal to have done more than he outlined, for here time was a factor that should be more considered. If anyone would pick up the volume recently published by Rollier he would be impressed with the remarkable results obtained on the mountain tops with tuberculosis patients. If they believed that this treatment owed its beneficial results to the abundance of ultraviolet rays in the sunlight on high mountains they must believe that there was something in this concentrated sunlight treatment. Dr. Kosmak had recently told him that he believed in placing a patient with post partum sepsis on the roof in the fresh air and sunlight as quickly as possible. If the sunlight helped these conditions why should not concentrated sunlight (ultraviolet rays) be of some value? He believed it was a very important factor in the treatment of gynecological conditions.

Emptying the Uterus in the Early Stages of Pregnancy with the Aid of Pituitrin.—Dr. JACOB L. BUBIS of Cleveland, Ohio, presented this paper. He said that in cases in which emptying the uterus was indicated, many physicians having begun to remove a dead fetus or retained placenta, were compelled to stop in the midst of their work on account of the alarming hemorrhage, and either use hot irrigations to stimulate uterine contractions or pack the uterus with gauze and let nature finish the work for them. It was, however, possible to empty the uterus in the early stages of pregnancy within a few minutes with the aid of pituitrin and a curette, the patients losing very little blood and suffering no collapse or shock even in the most severe cases. No hot irrigations were required to assist the expulsion of the fetus or placenta, nor were any hot irrigations or packing used after emptying the uterus. After citing several typical cases the writer summarized as follows: 1. Preliminary packing of the cervix and vagina to induce softening of the cervix and to stimulate uterine contractions was usually unnecessary. 2. No packing was placed in the cervix or vagina after emptying the uterus. 3. The injection of pituitrin was given after the cervix had been dilated, while the patient was under an anesthetic, the dose of pituitrin being one c.c. 4. Very little blood was lost while removing the placenta piecemeal. 5. The uterine cavity decreased in size as rapidly as its contents were removed. 6. No hot irrigations were necessary. 7. The total operation took only a few minutes.

Dr. ARTHUR STEIN stated that the question arose as to whether it was always necessary to employ pituitrin injections in cases of this type. He did not think that any gynecologist had ever seen a bad hemorrhage following curettage if the operation had been done properly and all the uterine contents had been removed. The use of pituitrin was a good thing, but it was not absolutely necessary in cases of abortion. The use of pituitrin in incomplete abortion he did not believe to be entirely satisfactory, and it certainly could not take the place of the curette. An important field in which they could use pituitrin was in giving the injection before doing an abdominal or vaginal cesarean section. They had used it in 22 cases with marvelous results. The operation was practically bloodless after its use. When the operation was started 1 c.c. of the solution was administered and then the uterus would contract and they could proceed with a bloodless operation.

Dr. JOHN O. POLAK stated that he had had 20 cases of incomplete abortion in which pituitrin had been employed without curettage, and spontaneous evacuation had not occurred in any of them. So far as the use of this agent was concerned he felt that in abortion it was ineffectual and retarded rather than favored the evacuation of the contents of the uterus.

Dr. SAMUEL W. BANDLER said he had had considerable experience with pituitrin during curettage. Dr. Bubis had spoken of the use of iodoform packing for the purpose of softening the cervix, but this was not the reason that iodoform gauze packing was indicated. Dr. Bandler said that if one found that abortion was inevitable, then in order to dilate the cervix he advocated the introduction of iodoform gauze into the cervix

and packing the vagina thoroughly with iodoform gauze. Ergotole should then be administered by way of the mouth. At the end of forty-eight or seventy-two hours, when the gauze was removed the ovum would often be found separated from the uterus and could at once be readily removed by the placental forceps. The more he had seen of these cases the more firmly had he decided not to attempt any dilatation of the cervix with instruments. He had curetted many of these cases and bleeding had never been so profuse as to cause him to stop. When the ovum was intact he never used a sharp curette, but always one blade of a placental forceps. If one emptied the uterus and then scraped away what was adherent to the placental site, that alone would make the uterus contract. This contraction was not entirely the effect of the pituitrin, although it might be of some assistance. Dr. Stein had referred to the use of pituitrin in cesarean section, and he had himself, after giving pituitrin, seen the uterine contraction so pronounced that after the uterus was incised there was often some difficulty in extracting the baby. Pituitrin was a wonderful agent in the labor stage, or when the uterus was emptying itself of a baby. It was possible that in an abortion if the ovum was completely separated from the uterus, the use of pituitrin might cause the ovum to be expelled. In inevitable or incomplete abortion ergotole was of the greatest value taken by mouth or by needle during the act of emptying the uterus.

Dr. HIRAM N. VINEBERG said he would not let such statements go unchallenged. He did not believe in emptying the uterus at the second, third or fourth month by packing with iodoform gauze. To him this was a very dangerous procedure. He knew of at least two deaths that occurred as the result of temporizing with gauze tamponading, one case at the fourth month and one at the eighth week. He knew of other instances in which severe infection had followed such a course. In infectious cases gauze simply dammed back the discharges and was a very dangerous thing, providing a good medium for the growth of bacteria.

Dr. MAX ROSENTHAL reported the case of a woman who entered the hospital after the fetus had died several hours previously with but slight pains, and who was very anxious to return home as soon as possible. There was no dilatation of the os. He told the house surgeon to give her 1 c.c. of pituitrin at 2 P.M., and he saw her at 3 P.M. When he arrived the stillborn baby had arrived. The woman was seven and a half months pregnant. This was the only instance in which the pituitrin worked so quickly. In no case of incomplete abortion had he seen any result from the administration of pituitrin in really expelling the fetus.

Dr. BUBIS, in closing the discussion, said that in cesarean section if the pituitrin was given after the abdomen was opened it did not in any way interfere with the delivery of the child. It should be borne in mind that in country practice one could not always return and remove the packing although it was best in cases of retained placenta to remove it as soon as possible. He always used the sharp curette and had never experienced any trouble with his method. A placenta at three months or more would often cause considerable bleeding when an attempt at removal was made. The uterus would be found quite flabby, and if great care was not used it might be penetrated by the instrument; with the use of pituitrin one had practically a firm wall on which to work.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, February 2, 1916.

Dr. WILLIAM J. TAYLOR, VICE-PRESIDENT, IN THE CHAIR.

Pharmaceutical Superstitions.—Dr. HORATIO C. WOOD stated that the clinical usefulness of any drug could not be determined alone by empiricism or laboratory investigation, but should be based rather upon a combination of reason and experience. The belief of Churchill, who introduced the compound syrup of hypophosphites that consumption was due to deficient oxidation in the body, and that the hypophosphites would correct this fault was said to be incorrect. The hypophosphites were eliminated unchanged and had practically no effect upon the system. Basham's mixture, used by many as a sort of specific for nephritis, while containing iron which might be indicated in cases of diseased kidney with anemia, could have no action upon

the kidney itself. Basham had distinctly recommended it for its chalybeate action. The astringency of the preparation interfered with its value as a hematinic. Neither this nor any other preparation of iron, the author said, exercised any real curative action in Bright's disease. Lithium had been introduced by Garrod with the idea that it would increase the solvency of uric acid in the blood and thereby prevent the deposit of urates in the joint which he believed to be the cause of the gouty symptoms. In the doses in which they could be given to human beings, however, without causing serious poisoning it had been shown that lithium salts did not increase the solubility of sodium urates. The action of lithium could not be explained by its diuretic effect since its salts were no more active diuretics than the corresponding salts of sodium or potassium. The widespread use of lithium Dr. Wood declared to be dependent chiefly upon the beneficial effect of the so-called lithia waters, but these waters contained such small amounts of lithium that in order to get a dose of five grains a person must drink 30 gallons of water. Manifestly, therefore, the benefit was due to the water and not to the lithium. The use of opium as a local remedy was said to be based upon superstition; the combination of lead water and laudanum used as an embrocation was declared to be highly irrational; while opium was mildly irritant, there were other drugs much more valuable for counterirritation. The use of the opium suppository in pelvic disorders was said to have no reasonable foundation, its action being purely systemic, quieting the pain of the irritated bladder as would a hypodermic of morphine. The aromatic spirit of ammonia, so widely used as a circulatory stimulant, it was shown could have no direct action upon the circulation. Ammonium salts when administered by the mouth were immediately carried to the liver where they were broken up into urea and hence never reached the heart. When given hypodermically they were carried to the heart before going to the liver and therefore might exercise a stimulant action. Even this effect, however, lasted only about ten minutes and could therefore scarcely be of practical value. The beneficial effects observed to follow the oral administration of ammonia were regarded as probably reflex from irritation of the gastric mucous membrane and were quite analogous to those seen from the use of smelling salts.

Overactivity as a Potent Factor in the Etiology of Some Functional and Organic Nervous Diseases.—Dr. ALFRED GORDON presented the results of his study from the standpoint of the principle of nervous exhaustion in this series of cases comprising functional and organic nervous diseases. It was observed that individuals suffering from the same disease did not have the same parts of their body affected. Inquiry had been initiated regarding the cause of this variability. Cases of occupation neuroses, lead intoxication, pernicious anemia, progressive muscular atrophy, poliomyelitis, paresis and tabes had been studied from the above standpoint. He was not in accord with the principle first enunciated by Weigart and Roux upon the energy of cells surrounding a diseased cell and later clinically and experimentally elaborated by Edinger. In connection with the occupation of the patient and the greater efforts used by one part of the body than by another, attention was called to the effect of overfunction of organs upon their early morbidity. Dr. Gordon believes that a body potentially diseased, or under the influence of a disordered metabolism through the presence of a toxic material would develop morbid phenomena primarily in parts functionally exhausted. Early treatment with removal from the usual occupation at the earliest possible moment tended to prevent localized morbid manifestations.

A Study of Signs and Symptoms of Autonomic Disturbance in Pulmonary Tuberculosis.—Dr. MYER SOLIS-COHEN observed that while little attention has been paid by writers upon tuberculosis to the manifestations of autonomic disturbance, the larger number of cases of pulmonary tuberculosis showed autonomic disturbance. Of the 109 patients forming the basis of the study 37 were males and 72 females. The ages ranged from ten years or under to seventy years and the various stages of pulmonary tuberculosis were exhibited. The autonomic phenomena observed in the patients were: Dermographia in 92 per cent of males; 82½ per cent of females. Enlargement or prominence of the thyroid gland in 72½ per cent of males; 77½ per cent of females. Tricolored nails in 54½ per cent of males;

69½ per cent of females. A showing of the sclera above or below the cornea upon opening the eyes widely in 63 per cent of males; 48½ per cent of females. A similar showing of sclera without widening of the palpebral fissure in 50 per cent of males; and 60 per cent of females. Sweatings exclusive of night sweats in 33½ per cent of males; 54 per cent of females. Migraine in 11 per cent of males; 62 per cent of females. Flushing in 22 per cent of males; 56 per cent of females. The production of a black line by drawing silver across the face in 28½ per cent of males; 44 per cent of females. Urticaria attacking at some time 25 per cent of males; 46 per cent of females. Subjective symptoms of cold 16 per cent of males; 27 per cent of females. Elevation of the eyebrows upon opening the eyes widely 42 per cent of males; 26 per cent of females. Asthma presented at some time in 17½ per cent of males; 20½ per cent of females. Burning, especially of one side of the face or one part of the body in 6 per cent of males; 24½ per cent of females. Angioneurotic edema in 10½ per cent of males; 28 per cent of females. Bleedings or tendency to bleeding, exclusive of hemoptysis in none of males; in 29 per cent of females. Subjective sensations of heat in 6 per cent of males; 26½ per cent of females. A showing of the sclera above or below the cornea on fixation in 23 per cent of males; 11 per cent of females. Hay fever in 12 per cent of males; 6 per cent of females. In connection with the general nervous and vasomotor symptoms other than those enumerated it was noted that of the 47 patients exhibiting nervous symptoms (12 males and 35 females) 23 were between the ages of twenty-one and thirty years, 43 were in the incipient stage of the disease, 27 were latent cases and 23 gave a tubercular family history.

Dr. HORATIO C. WOOD, JR. protested against Dr. Cohen's use of the word "autonomic," which term he felt was used at the present time with an unfortunate degree of ambiguity. Dr. Cohen had apparently used the word as synonymous with sympathetic. In this country, however, Dr. Wood said that physiologists and pharmacologists divided the sympathetic system into two parts,—the sympathetic proper, and the autonomic system. Most of the phenomena to which Dr. Cohen had referred were vasomotor phenomena, and the blood-vessels, with the exception of those of the face, Dr. Wood said, were supplied from the sympathetic proper and not from the autonomic system. In his opinion it would have been much more in accordance with the common use of the word to have spoken of sympathetic phenomena rather than autonomic phenomena. How migraine could come from either the sympathetic or the autonomic system was not clear to Dr. Wood, since neither of these systems of nerves had any connection with the nerves of sensation. The thyroid gland nerve supply, it was observed, was at present purely hypothetical.

Preparedness of the Medical Department for War.—Lt. Col. H. C. Fisher states that attempts have been made to place medical property with the organized militia, but before reserve supplies are issued to a State the Governor must certify the requisition that he has facilities for caring for the same. In some instances units have been broken up to such an extent that it has been impossible to collect the property pertaining to them. This would be a serious matter in time of actual hostilities.—*The Military Surgeon.*

Intracranial Hemorrhage without Symptoms of Compression.—Lam and Law report a case of a man, aged thirty-two, who was thrown from his bicycle by collision with a cart and his head knocked against a post. He was admitted to the hospital an hour later in an unconscious condition and died ten days later. At no time did the patient show any symptoms of compression, except an attack of vomiting two hours after admission and the unconsciousness from which he could be partially aroused. A small, superficial scalp wound was present over the right parietal eminence. Autopsy revealed a very fine fissure extending from the right parietal bone, downwards and forwards, into the greater wing of the sphenoid in the middle fossa of the skull. An extradural blood clot, 2½ in. by 2 in., corresponding to the temporal lobe of the brain was found, but the brain showed no flattening at this point. The membranes and surface of the brain were congested and edematous, but the interior showed no changes. Such a case presents difficulty in diagnosis.—*The Lancet.*

Miscellany.

Sanitary Condition of Bottled Waters.—The Bureau of Chemistry of the United States Department of Agriculture has for several years been investigating the sanitary conditions in the production and distribution of bottled mineral and table waters, which are offered for sale in interstate commerce and are, therefore, subject to the Food and Drugs Act. It has recently conferred with a number of sanitary experts and bacteriologists regarding a desirable standard for judging the condition of such waters. As a result of the investigations and conferences, the conclusion has been reached that the tolerances established by the Public Health Service of the Treasury Department for waters served on interstate carriers are none too rigid for application to bottled waters sold in interstate commerce or imported from foreign countries. These standards are as follows: (1) The total number of bacteria developing on standard agar plates, incubated for twenty-four hours at 37° C., shall not exceed 100 per cubic centimeter, provided that the estimate be made from not less than two plates showing such numbers and distribution of colonies as to indicate that the estimate is reliable and accurate. (2) Not more than one out of five 10-c.c. portions of any sample examined shall show (by the method of the Public Health Service) the presence of organisms of the *B. coli* group.

Treatment of Trachoma.—The Annual Report of the Surgeon General of the United States Public Health Service states that the best solution of the trachoma problem has been found to be the establishment of small hospitals for the treatment of the disease in localities in which it is prevalent; and that the service, therefore, now maintains five trachoma hospitals in the three States of Kentucky, Virginia, and West Virginia. In the past fiscal year 12,000 cases of the disease were treated, and in addition the hospitals have been used as centers for educational work. Doctors and nurses have been sent out from them to visit the homes of the patients and explain how the development and recurrence of the disease may be prevented. In Kentucky alone, during the year, 1,308 such visits were made. In Kentucky also, surveys were made in sixteen counties, and of 18,016 people examined 7 per cent were found to be suffering from trachoma. A special feature of the work has been the giving of lectures and clinics before medical societies in various counties where trachoma hospitals could not be established. Patients were operated on in the presence of physicians and the most modern methods of treatment were demonstrated.

The Disposal of Municipal Sewage.—A sewer district in the city of El Dorado, Ark., constructed a septic tank for disposing of sewage. An owner of land near the septic tank brought suit for damages, alleging injury to his property. It was proved that offensive odors emanated from the tank and that a stream which flowed through the plaintiff's land was polluted. The evidence showed, however, that much of the pollution of the stream was caused by unnecessary flushing of the tank. The court held that the sewer district was liable for the amount by which the value of the plaintiff's land was depreciated by reason of the construction and operation of the septic tank, but that no damages could be recovered against the municipal authorities because of the acts of employees in unnecessarily flushing the tank.—Public Health Reports, Nov. 19, 1915.

PATHOGENY OF DIABETES AND FECAL DISINFECTION.

By G. DELGADO PALACIOS, M.D.,

CARACAS, VENEZUELA.

PROFESSOR OF PHYSIOLOGICAL CHEMISTRY AT THE UNIVERSITY OF CARACAS.

THE primitive phenomenon of the pathogenic mechanism of diabetes mellitus is to be found in an *excess above normal of ammoniacal and acid fermentations of the large intestinal contents*. In accordance with this conception diabetes must be considered as a disturbance of metabolism of fecal origin.¹ This does not mean that the cause of the disease is exclusively external because there are also internal propensities that predispose the organism to the production of this ammoniacal and acid dyspepsia. This fecal intoxication of the organism satisfactorily explains not only the principal symptoms and anatomico-pathological changes of the disease, but also its great variations, like the absence of diabetic coma in certain countries (Venezuela), a fact chemically and clinically well established. The excess above normal in the simultaneous production of ammonia and volatile fatty acids explains the polyuria, the acidosis, the glycosuria, the presence or absence of diacetic acid in the urine, the calciuria or exaggerated loss of calcium in the urine, etc. The physiological influence of the pancreas upon digestion and upon certain phases of carbohydrate metabolism becomes more or less impaired as a consequence of this persistent fecal intoxication, which tends to degenerate the islands of Langerhans. The favorable influence of prolonged fasting and restricted diet may be explained by their disintoxicating effect upon the digestive tract. Fecal disinfection is nevertheless the radical treatment of diabetes, both preventive and curative.

Polyuria and Acetonuria.—In the common conditions of human life, a part of the urea, small as it may be, proceeds directly from intestinal putrefaction; that is to say, it is the product of chemical transformations which take place outside the normal tissue catabolism. This part of the urinary urea must receive the name of extraphysiological or putrefactive urea.² In certain well-determined conditions this putrefactive urea is accompanied by the excretion of a corresponding proportion of acetone. In diabetics the putrefactive polyuria and acetonuria reach a high degree. In this connection it must be remembered that Minkowski³ foresaw the existence of putrefactive urea in experimental diabetes, when he refused to accept the name "diabetes without glycosuria" that was proposed by Hedon to designate the cachexia that sometimes follows the partial extirpation of the pancreas without carbohydrate disturbance.

If a solution of an ammoniacal salt of a volatile or inferior fatty acid is introduced into the rectum and its entire absorption permitted, the result to be observed is that the twenty-four-hour excretion of urine and the amount of urea increase. When butyrate of ammonia is the salt employed the urinary acetone greatly increases. If the rectal injections are continued for many days the polyuria and acetonuria reach a high degree. In two series of experiments the following variations were observed: volume, from 1 to 3 liters; urea, from 10 to 18 grams; acetone from 5 to 245 mg.

To prove that really there is present in the normal large intestine, in a given moment or during a certain time, a greater amount of ammonia and volatile fatty acids than the quantity which goes out with the feces every twenty-four hours, a direct method has been employed, which consists in the quantitative estimation of these compounds in spontaneous stools and those provoked by saline and drastic purgatives. The difference between the two series of determinations referred to the same subject gives the quantities of both compounds that have passed into the liver, and there been transformed into urea. The conclusion to be drawn therefrom is that, in the common conditions of human life and in normal subjects, an average of 300 mg. of ammonia is produced every twenty-four hours in the large intestine as a result of putrefactive processes (in some cases this quantity has amounted to twice as much), and that this ammonia, after having been absorbed into the blood, appears in the urine as 0.5 gram or even 1 gram of putrefactive urea. To this daily amount of putrefactive urea corresponds normally the production of several milligrams of acetone when the putrefactive salt produced in the intestine is the butyrate of ammonia or certain other fatty salts of ammonia. The average quantity of volatile fatty acids produced and absorbed, free and combined, in twenty-four hours amounts in normal persons to 5.4 grams expressed as acetic acid.

These quite remarkable figures are not exaggerated if we consider the intensity of intestinal putrefaction, the quantity of material there modified, the intestinal stasis, and the degree of fecal reabsorption. Some data concerning this subject are here given. More than 25 per cent. of the total organic matter of the feces is composed of residual bacteria.⁴ The bacteria absorb up to 46 per cent. of the total fecal nitrogen and metabolize a greater amount of it.⁵ Most of these bacteria are killed in the struggle for life between them and the organism; therefore a minute fraction of the total fecal bacteria microscopically visible can be brought to development on artificial culture media.⁶ The residual alimentary material remains in the large intestine for three-fourths of the twenty-four hours.⁶ The small intestinal contents travel with twenty-five times

more rapidity than the large intestinal contents.' The fecal matter contains five times more water and three times more nitrogen when it passes the ileocecal valve than when it leaves the rectum."

Computations based upon experimental investigations in dogs and on man give figures for both compounds even more remarkable than those referred to.

Vaughan Harley's experiments¹ permit to form an idea of the volume of fecal aqueous extract and putrefactive nitrogen that fecal reabsorption carries daily into the blood. The method followed by this investigator is the comparative analysis of urine and feces of dogs after removal of the large intestine with that of normal dogs on precisely the same diet. The conclusions from these experiments which are of special interest for us are: (1) The increase in quantity of feces is principally due to the increase in quantity of water, the total quantity being nearly five times as much as in the case of normal dogs. (2) The quantity of nitrogen in the feces is increased to nearly three times as much as in normal dogs. (3) Ten per cent. at least of the nitrogen of the diet is absorbed in the large intestine. The normal weight of the whole in the case of a man on the mixed diet indicated by Schmidt and Strasburger,² is 251.1 grams for three days, with 77.79 per cent. of water. A simple calculation shows that in man near *one-third of a liter of aqueous fecal extract passes into the blood every twenty-four hours*. The quantity of proteins and nitrogenous compounds that have not been digested and absorbed in small intestine form a nitrogenous stock three times larger than that which is found in feces. The difference between these two quantities is eagerly destroyed and utilized by putrefactive bacteria, and it is only the products of the catabolism of these bacteria, principally the ammonia, which are absorbed into the blood and disappear from the large intestine. In the mixed diet proposed by Schmidt and Strasburger, the amount of nitrogen which must disappear by fecal reabsorption must be 1.6 grams, the total diet nitrogen being 16 grams. If we accept that only 25 per cent. of this nitrogen is absorbed as ammonia, the quantity of putrefactive urea produced every twenty-four hours would amount to 0.8 gram. This proportion of 25 per cent. is not exaggerated. H. Fischer³ has found that a meat diet stool obtained by means of a laxative (Stool No. VI) and abandoned to its spontaneous putrefaction for twenty-four hours developed 47.6 per cent. of ammonia-N as compared with the total nitrogen of the stool. Had H. Fischer made the quantitative estimation of ammonia in that stool as soon as it was evacuated he would very probably have changed his opinion regarding this ammoniacal putrefaction. The after-putrefaction of a stool really occurs but very slowly and late, after the second day;⁴ the greater part of determined ammonia was evacuated with the stool. This experiment, however, is very interesting because it gives us the opportunity of studying the whole production of ammonia when a stool is obtained by means of a laxative; that is to say, when the nitrogenous and putrefactive matter is not yet exhausted within the intestine. The observed high proportion is not surprising if we remember there are in the intestine some bacteria, like the *Proteus vulgaris*, which produced up to 36 per cent. of ammonia-N of the decomposed albumin-N.⁵

The above figures are confirmed by some direct investigations on patients with cecal fistula. The

observations of Macfadyen, Nencki, and Sieber⁶ was carried out on an old woman of 40 kilos weight, and those of Ciechowski and Jakowski⁷ were also on two women. The average weight of the diarrheic stool which issued almost constantly from the cecal fistula in the last two cases and in the former one, when the patient was submitted to two different diets, is given in the following table:

	Variations	Average Weights, Grams
No. 1 (C. and J.)	80-680	380
No. 2 (C. and J.)	220-400	310
No. 3 (M. N. and S.)	230-550	390
No. 4 (M. N. and S.)	390-515	452
Average		383

In order to obtain an idea of the amount of material which disappears in the large intestine the normal stool of Schmidt and Strasburger can provisionally be accepted as a term of comparison. This computation thus established is only approximate, and probably must be higher because the test meal as given by Schmidt and Strasburger is more abundant than that which was used by Macfadyen, Nencki, and Sieber in their woman patient. The following table shows the percentage and quantity of each compound in the ileum stool and in the rectal stool:

ILEUM STOOL. WEIGHT: 383 GRAMS		
	Percentages	Amounts, Grams
Water	95.00	363.85
Solid extract	5.00	19.15
Nitrogen (of the solid)	6.08	1.16
Carbohydrates (of the solid)	45.00 (as acetic acid)	4.30
Sugar	2.50	4.79
Acidity (as acetic acid)	0.15	0.57

RECTAL STOOL. WEIGHT: 83.7 GRAMS		
	Percentages	Amounts, Grams
Water	78.40	65.60
Solid extract	21.60	18.10
Nitrogen	5.50	0.99
Carbohydrates	2.59 (as acetic acid)	0.23
Volatile acids H. Ury		0.91
Sugar	0.00	0.00

DIFFERENCES: AMOUNTS ABSORBED IN THE LARGE INTESTINE		
Water		298.20
Acetic acid		8.52
Nitrogen		0.17

Some observations are necessary for the right interpretation of this table. The proportion of absorbed acids is too large because the ileum stool does not always contain sugar (in two of the four studied cases). It must be observed that the Macfadyen, Nencki, and Sieber woman received 60 grams of sugar, and this substance appeared also in one patient of Ciechowski and Jakowski. When the diet contains much sugar, this substance reaches the cecum, but there it disappears very soon by fermentation, because the feces never contain sugar. When the quantity of sugar in the diet is excessive, or when, and this is very important, a large quantity is *injected into the blood*, the feces contain sugar as soon as diarrhea is produced;⁸ that is to say, when fecal concentration is not produced. This is a sure indication that sugar is always excreted

into the cecum in these conditions: it is passed out when diarrhea carries it out; when not, it disappears by fermentation and absorption. The carbohydrate estimated by Macfadyen, Nencki, and Sieber was a whole determination obtained by difference, while in the test meal the determination refers only to that attackable by HCl at 2 per 100. The nitrogen absorbed is too low because the test meal is more abundant and rich than the patient's diet. Nevertheless this comparison is very illustrative though made between two dissimilar cases.

It is easy to infer what a profound perturbation intestinal putrefaction induces in the human organism. The putrefactive urea in reality is nothing other than the hepatic product of residual ammonia from catabolism of bacteria, while the physiological urea originates from the residual catabolism of tissues or of physiological digestion process. The size of bacterial growth taking place constantly in the intestinal contents depends, as is the case in the development of every living thing, upon the quantity of food on which it thrives. If the alimentary residues are abundant, the intestinal stasis prolonged, and the defensive or antiseptic natural power of the intestinal walls weakened, then the intestinal flora reaches its maximum degree of development. All these conditions reach their maximum degree in diabetes.

A normal intestine is that which, besides the bactericidal activities of its epithelium, effects the elaboration, absorption, and expulsion of the remainder of the food, in order that the least possible of waste material is left for the bacteria. The intestine, however, has a certain capacity that can be surpassed by the excessive quantity of ingesta. This has been recognized by many medical authors and in a practical way by many laymen. In order to diminish the quantity of bacteria produced in the intestine a food easily assimilable must be ingested and, above all, the quantity of food must be restricted. In this way Strasburger found in a woman patient, who for a long time had ingested daily 1 liter of milk and one or two biscuits, that the quantity of dry bacteria in her intestine amounted to 2.95 grams; that is to say, a little more than a third of the value found in normal conditions. In diabetes, on the contrary, the polyphagia compels the patient to eat many times above the digestive capacity of his intestine; he eats more for the nutrition of his intestinal bacteria than for the nutrition of his own organism. An abundant residual waste accumulates in the intestines and the stools are very large. It is easy to understand that in these conditions the bacterial, both fermentative and putrefactive, must reach their greatest development; consequently the production of ammonia and volatile fatty acids must be very abundant, provided the excess of nitrogenous substances and carbohydrates and the bacteriological conditions are favorable, as always happens in this disease. Medical authors agree that diarrhea is a very uncommon symptom in diabetes; on the contrary, constipation appears later in the disease, and when obstinate, in Tyson's experience,¹⁶ is an unfavorable symptom. This condition is decisive because fecal reabsorption cannot take place without a concentration of the feces. The fecal putrefaction and reabsorption are more pronounced when intestinal stasis is present, which may exist although defecation occurs every twenty-four hours. Fecal reabsorption can occur, but only to a slight degree, when diarrhea exists. In this case the retention of the

food and its products in the entire intestine is a question of only four or five hours." When extensive intestinal stasis exists putrefaction takes place also in the small intestine.

Fecal reabsorption is very pronounced during constipation as has been established by direct analysis of the feces. While the healthy adult daily excretes 0.99 gram of nitrogen, the habitually constipated patient under the same diet excretes only 0.52 gram. Thus, in constipation the percentage of nitrogen is the least in comparison with other conditions.

N-percentage in constipation (S. and S.)	4.57 per cent
N-percentage in constipation (H. Fischer)	1.36 per cent
N-percentage in diarrhea (S. and S.)	6.74 per cent
N-percentage in healthy adult (S. and S.)	5.00 per cent

The percentage of utilization of cellulose from the total amount ingested reaches also its maximum during constipation, as the following figures show:

Healthy adult	57.9 per cent
Chronic habitual constipation	81.4 per cent
Fatty diarrhea in pancreas disease	20.9 per cent
Diabetes with normal gastrointestinal tract	78.9 per cent

I have determined the percentage of soluble calcium (expressed as CaO) contained in the aqueous extract of feces compared with the total calcium of the feces and have found the following comparative figures:

Healthy adult	10 per cent
Polyuric calciuria with constipation	4.2 per cent
Polyuric calciuria without constipation	50-60 per cent
Diabetes by means of a laxative	95.7 per cent

The above stated led to the conclusion that the retention of feces in the large intestine during constipation produces an advanced degree of concentration, so that water is reduced 60 per cent., and with it all soluble or destroyable compounds tend to disappear from the feces.

The watery diarrhea-like stool from the small intestine, which pours almost constantly in the cecum, carries a rich material for the putrefactive bacteria metabolism of the large intestine; this material consists of nitrogenous waste products three times greater in amount than that which passes out, a small proportion of sugar and peptone, lactic acid, and some other fermentative products, which must be finally reduced to a fifth part of their primitive weight or volume. Consequently, in the common conditions of human life, with three or four daily meals, the contents of the large intestine are in a state of continuous putrefaction. A purgative causes the expulsion of the contents of the large intestine during a certain time, eight hours for example, and supposing that this action does not interfere with the putrefactive process, the quantitative estimation of the putrefactive products in the ejected material can give but a slight idea of the amount produced and reabsorbed in twenty-four hours. The supposition that this quantity must be three times greater than the actual estimation is manifestly below the reality. Probably the multiplication of the quantity determined in a spontaneous stool by four is a surer way of approaching the reality. H. Fischer has found with his method of laxative and after-putrefaction of the stool that the quantity of ammonia in the feces calculated in the dry solid becomes five times greater under the same diet; thus: Meat diet (average of three cases) 593.1 mg.; laxative stool and after-putrefaction, 3,094.8.

Our investigations by means of purgatives have been made during fasting, that is to say in the morning. The only time I have used a purgative at

noon, after breakfast, I have obtained in a normal person a proportion of ammonia twice as much as in the others (case B de T.). Five diabetics have been investigated by this method. Three of them have given the following quantities of ammonia and volatile fatty acids calculated as acetic or butyric acid.

	Ammonia, Mg.	VOLATILE FATTY ACIDS	
		Acetic Acid, Grams	Butyric Acid, Grams
C. R.	425	4.15	6.09
M. T.	511	4.72	6.93
C. G.	574	5.52	8.10
Average ..	503	4.79	7.04

The urinary volume and acetone were:

	Urinary Volume, C.c.	Acetone, Mg.
C. R.	2377	328
M. T.	3518	398
C. G.	3027	245

The same computation as above gives for twenty-four hours the average figure of 1,500 mg. for the ammonia or 2.66 mg. of urea; and 14.37 grams of acetic acid or 21.12 grams of butyric acid. The urine did not contain diacetic acid or β -oxybutyric acid, as is the rule in the country.

The fourth case investigated was in a patient suffering from severe diabetes, with very abundant polyuria and glycosuria. The purgative produced only a pasty stool of natural consistence. The following table gives the result of the chemical investigation of the feces and urine:

Weight of the stool.	1,239.0	grams
Ammonia.....	0.556	
Volatile fatty acids as acetic acid.....	9.55	
Urine of twenty-four hours.....	12,950.0	c.c.
Volatile fatty acids as acetic acid.....	5.03	grams
Sugar.....	468.3	grams

In this case the computation must be four times the above stated figures: 2,224 grams of ammonia or 4.76 grams of urea; 38,232 grams of acetic acid or 56.07 grams of butyric acid for twenty-four hours. Very probably there is a miscalculation here, because the urine contained 2,631 grams of ammonia and 40.83 urea. In this remarkable case of diabetes it is not possible to explain the extreme polyuria of 13 liters every twenty-four hours by the putrefactive urea, because the colossal amount of sugar excreted in the urine is here the principal factor as a diuretic element. When the quantity of sugar excreted is moderate, from 50 to 130 grams, the diuretic effect of the sugar cannot be invoked because there are many cases in which the volume of the urine may amount to 3 liters with 20 or 30 grams of sugar, and others with 1.5 liters and 130 grams. The patient had had diabetes for one year when I made the analysis of his feces and urine; the daily amount of urine has varied between 7 and 12 liters. He has never had diabetic coma nor has his urine given the Gerhardt reaction. His urine does not contain butyric nor β -oxybutyric acid, only acetic and formic acids. It is an acetic diabetes like every case observed in Venezuela. In the temperate zone diabetes in man is a butyric diabetes, that is to say, the butyric germs are principally the agents. The butyrate of ammonia is produced in the intestine in the tropical

Atlantic region, but as a consequence of the bacterial decomposition of protein. For example, one kilo case may yield 117 grams of fatty acids containing 47 grams of butyric acid. This explains the production of acetone in the urine from butyric acid not produced by direct fermentation of carbohydrates. A similar explanation may be given of the almost complete absence of diabetic coma in the dog and the absence of diacetic acid in his urine.

To vary the experiment the diabetic M. T. was given a rich meat diet with a breakfast of 500 c.c. of milk and coffee, bread and butter. After three days a violent cathartic was administered early in the night. The following is the result of this investigation, which has not previously been published:

	Weight	Ammonia	Vol. Acids
Spontaneous stool.....	285.0 g.	215 mg.	143c.c.n/10
Diarrhoeic stool.....	1248.0		
Solids, per cent.....	4.1		
Total solids.....	51.16		
Ammonia-N.....	1.266		
Total nitrogen.....	4.320		
Ammonia-N.....	29.3		
Total-N.....	1.538		
Ammonia.....	3.006		
Ammonia per 100 g. of solids.....	5.35		
Volatile fatty acids (acetic acid).....	0.634		
Water-soluble calcium (CaO).....	1.006		
Total calcium (CaO).....	63.02		
Soluble calcium per cent.....			

The difference of ammonia multiplied by three produces 4 grams, more or less, of ammonia or 7 grams of urea. Here it must be remembered that the same quantity of ammonia in combination with butyric acid has occasioned a polyuria of 3 liters. I doubt if ever such amount of ammonia will be found in a human intestine. Probably in this case the excessive meat eating and the intestinal stasis were the cause of this remarkable development of ammonia. We must realize that ammonia does not accumulate in the feces and pass into the blood with more rapidity as the water itself is absorbed. The absorption coefficient of ammonia is very high, in comparison with other intestinal gases, at 0° C., and 760 mm. Hg. pressure.

Ammonia.....	1298.9
Hydrogen sulphide.....	4.686
Carbonic acid.....	1.712
Hydrogen.....	0.020

The experiment which resulted in a revelation regarding the quantum of this intestinal reabsorption of ammonia salts was that established at the beginning with butyrate of ammonia, showing the increased urea and above all the increased acetone. The acetone in this particular case amounted to 398 mg. in twenty-four hours, and this quantity of acetone can be produced by the intestinal absorption of 38.3 grams of butyrate of ammonia or other equivalent salts.

Similar consideration to those stated above are applicable to the production and reabsorption of acids; the quantity that direct investigation may detect is only a fraction of the whole produced. In diabetes a large proportion of volatile fatty acids of external and putrefactive origin, that is to say, of abnormal constitution to the human tissues, invades the organism in an abnormal way, by fecal reabsorption, and passes directly into the liver. When organic acids enter the organism through the stomach and first portions of the intestine they

are principally combined with potassium and sodium. The small quantity of acids produced in these parts by pure fermentative action is also rapidly neutralized by the predominant alkalies of the intestinal juice and are absorbed. All these organic salts are therefore oxidized as fuel material. The acids of the large intestine are produced by putrefactive fermentative decomposition of amino-acids, lactic acid, fatty substances, and by a direct fermentation of carbohydrates and cellulose in a medium almost deprived of alkalies and oxygen. All the available calcium, magnesium, and ammonia are insufficient to neutralize them, and they enter by the enterohepatic way. In the liver they are transformed into sugar, so far as our most advanced knowledge in physiology can establish. The sugar thus formed is a sugar of abnormal origin and constitution. It is a sugar of putrefactive origin that cannot be stored up by the liver as glycogen and cannot be utilized by the tissues, being finally excreted in the urine.

Calciuria and Lipaciduria.—The substitution of butyrate of ammonia for acetate of calcium in the rectal injections has established the fact that the volatile fatty acids and the calcium of the urine increase simultaneously in relation not only to the normal series but also to the corresponding series of butyrate of ammonia. The volatile fatty acid which increases in the urine is precisely that which is injected into the rectum. The calcium protects the fatty acid from destruction in the organism, although this protection is not absolute—60 per cent, according to my experiments. While the butyrate of ammonia injection is well tolerated that of acetate of calcium produces a catarrhal irritation of the mucosa of the large intestine. In contrast with the diuretic effect of acetate or butyrate of ammonia the acetate of calcium produces a marked oliguretic effect. When both compounds are used together, in certain proportion, the polyuric effect of the ammonia salt predominates. In diabetes this simultaneous increase of fatty acid and calcium is generally, if not universally, observed. Many investigators have repeatedly observed the increase of the one or the other compound in diabetic urine. Rumph, C. A. Herter, and Wakeman have determined in the urine 86 c.c., 200 c.c., even 300 c.c. of decinormal fluid for the adult and 80 c.c. for a five-year-old boy. Neubauer, Gerhardt and Schlessinger, and Toralbo have verified the extreme loss of calcium. The latter has found the extraordinary figure of 2.58 grams for a diabetic who excreted 7,850 c.c. in twenty-four hours. I have myself verified the simultaneous increase of both compounds in diabetic urine.

The simultaneous increase of volatile fatty acids and calcium in the urine, when they are introduced into the rectum, and their simultaneous increase in diabetic urine strongly suggest the idea that the putrefactive fermentation of the intestinal contents in diabetics may be the primary cause of the observed calciuria and lipaciduria. This supposition is confirmed by the fact that calcium is to be found in the diabetic stool in a higher state of solubility than in the normal stool. While the normal feces contain 10 per cent. of soluble calcium, as compared with the total calcium, the aqueous extract of diabetic feces contains 50 or 60 and even 95 per cent. of the total calcium. It is not impossible, however, that exceptionally in a diabetic patient a proportion far below the solubility of normal calcium may be found, on account of pro-

longed constipation, during which time a reabsorption of almost all the soluble calcium of the stool may have taken place. I have found an anomalous solubility of 4 per cent. in the stool of a calciuric and polyuric but not glycosuric patient. Calciuric patients of this kind have in fact polyuria, calciuria, lipaciduria, acetonuria, hunger, and thirst, indeed every symptom of diabetes except glycosuria.¹ In the diabetic stool I have always found a very high degree of solubility of the calcium, even up to 95 per cent., and this solubility and the large quantity of fecal extract which passes into the blood in this disease explain the lipaciduria and calciuria. It is a known fact that diabetics have normal but very large evacuations, and late in the disease they suffer from constipation. The volume of fecal extract entering the blood in diabetics is consequently augmented many times above the normal, in the same proportion that their stools are larger than the normal ones. In the unusually severe case of diabetes referred to, with abundant polyuria and polyphagia, the fecal matter in the cecum and last portion of the small intestine must have reached a volume of at least five liters, as the weight of the patient's stool always exceeded one kilogram. As in this patient the soluble condition of the calcium reached 95 per cent. of the total stool calcium, that is to say, was entirely soluble, it is easy to deduce how large must be the quantity of calcium and volatile fatty acids that reached the urine. In fact the proportion of calcium is greater in the urine than in the feces, a condition the reverse of normal elimination as the following table shows:

Urinary CaO.....	2.226 grams
Urinary volatile fatty acids.....	838.5 c.c. n/10 c.c.
Fecal total calcium.....	1.121 grams
Fecal soluble calcium.....	1.073 grams
Soluble calcium, per cent.....	95.7 per cent
Fecal volatile fatty acids.....	1593.5 c.c. n/10 c.c.

The above figures make evident a large passage of the putrefactive calcium salts from the feces into the urine. This increased elimination of the calcium in the urine above the intestinal elimination has been recognized in diabetes by many authors such as Brugsh, Schlessinger, Allen, et al., but a true explanation of the phenomenon has not been given. This reversed passage of putrefactive calcium salts from the feces into the urine, what I have called "retrograde circulation of the calcium in the human body"² exists also in the normal state, but in a very slight degree. This explains the constant passage of a small proportion of volatile fatty acids in the normal urine, where they arrive protected by the action of the fecal calcium. It must be here stated that H. Ury³ has given another interpretation of the presence of soluble calcium in the feces. A thorough discussion of the question is to be found in my book,¹ pages 103-125.

A large amount of acidity of external or bacterial origin is produced in diabetic intestine by various means: by bacterial decomposition of fatty bodies, by fermentation of carbohydrates, celluloses, and hemicelluloses, by diamidation and decarboxylation of amino-acids. In the stomach and first portions of the small intestine the diabetic organism protects itself from acid intoxication by means of the alkalies of the digestive juices and the alkalies which the food carries with it; in the last portion of the small intestine and in the large intestine, the calcium, magnesium, and ammonia of the feces are present in as large amounts as possible. When the quantity of acid exceeds that which can be combined with these substances the liver produces sugar

in an abnormal way, which is destined to be eliminated in the urine.

Finally many authors have recognized the abundant urinary excretion of aromatic bodies, indican, and other pigments and compounds of putrefactive origin in diabetics. This is easily understood from what has been previously said of the intensity of fecal putrefaction and reabsorption. But the most important for us is that this augmented excretion begins with the first appearance of the disease. To-day it is considered that reduced carbohydrate tolerance is to be found in patients who are in a prediabetic condition. A. C. Croftan²⁰ has established that nearly all the patients who are in the prediabetic condition complain of a manifold clinical picture essentially dyspeptic and excrete an abnormally large amount of aromatic bodies in the urine, chiefly aromatic sulphates, indican over twenty milligrams per diem, and aromatic glycuronates.

Experimental diabetes in the dog is produced by means of fecal putrefaction and reabsorption. One may say that the dog has been especially selected for the production of experimental diabetes on account of the enzymic and bacterial condition of his alimentary tract, and also that the operation which is performed to produce diabetes is precisely that which is necessary to cause the predominance of fecal putrefaction over normal digestion.

In the dog the salivary gland does not contain diastase.²¹ In the pig and in man these salivary glands contain an abundance of ptyalin. In the dog the pancreas is the principal source of amylase of his digestive tract, probably of blood and urine diastases, and when the duct of this gland is ligatured the diastase in the feces diminishes considerably.²² Wakabayashky²³ has shown that in the dog the large intestine juice is 400 times less active than the pancreatic juice and that in the same animal the large intestine juice has from 25 to 50 per cent. the activity of the small intestine juice. In the sense here explained, the dog occupies an intermediary place between the pigeon and the rabbit. Like the dog the pigeon cannot digest cellulose or hemicellulose. Its entire intestinal enzymic activity is dependent upon the pancreas; when the duct of this gland is ligatured in the pigeon a rapid cachexia is developed, during which the animal is absolutely unable to assimilate the carbohydrates. It dies as it would from absolute deprivation of carbohydrates, and the addition of sugar has a marked influence in prolonging its life. When the pancreatic duct is ligatured in a rabbit an opposite phenomenon is to be observed. At the beginning the animal seems to suffer somewhat, but the operation has no permanent effect upon the health or life of the animal because the rabbit has a powerful mechanism to supply the lacking pancreatic juices. On the one hand, the salivary glands are active, and on the other, the animal has a great power of digestion of celluloses and hemicelluloses, and the vegetable food in its crude form brings with it natural diastases which facilitate the digestion of carbohydrates.

Partial pancreatectomy in the dog, with preservation of the pancreatic duct so as to avoid atrophy of the remnant of the gland, gives a more satisfactory reproduction of clinical diabetes than is afforded by von Mehring and Miskowski's total pancreatectomy or Sandmayer's method of slow pancreatic atrophy. If glycosuria does not appear upon a diet of meat and bread a second operation may

become necessary to remove a new portion of the pancreatic tissue. The continuation of the diet makes the glycosuria more and more intense. After a severe diabetes has been established by this means, autopsy reveals an "hydropic" degeneration of the islands of Langerhans. Suppose a second operation is performed on this dog as Homans²⁴ has done, e.g. ligature of the pancreatic duct. It has been found that, after duct ligation, on meat and bread no glycosuria appeared, the animal loses weight, and diarrhea appears. It is necessary to combine with carbohydrate feeding the administration of fresh pancreas to obtain glycosuria (the food is thus well digested, and diarrhea disappears). It has been recognized that when the pancreatic duct is ligatured in a dog the amylolytic ferment diminishes markedly so that bacterial *amylolysis* does not take place. The *Bacterium coli* and other fecal bacteria only ferment sugar.²⁵ Even dextrine is not attacked by them. These premises well established, it is easy to give a satisfactory explanation of the Homans experiment. In the absence of amylase the bread is not saccharified and partly transformed into an acid substance by bacterial action, indigestion supervenes, and fecal reabsorption and putrefaction do not take place. The pancreas tissue is found to be directly necessary to produce glycosuria on account of the amylase it supplies to the intestine. Let us fix now our attention upon the Rosenberg²⁶ experiment and the importance it has for experimental diabetes. The pancreatic ducts and the efferent blood vessels are ligatured. The atrophy of the pancreas develops progressively, but life is prolonged for ten months and a half, when eventually the animal dies of pleuropneumonia. All the time the animal has received a diet composed of meat and bread, and has never had dextrose or any form of sugar whatsoever in his urine. Some minute portion of glandular tissue has been preserved at the periphery through the capillary circulation. The question here is why these minute portions of pancreatic tissue left have not been atrophied. The rule is that they must atrophy after so long a time and with the animal on such a diet. They have not suffered because there has been no infection. That is the reason. Rosenberg clearly establishes the fact: "The estimation of the quantity of sulpho-conjugated acids when active pancreas is present is near 3.7-3.8 times greater than when it fails, which can be explained by the frequency of stools, which prevents the establishment of an intensive intestinal putrefaction." Here is an experiment which cannot be explained away. The atrophy of the pancreas is almost complete, the animal is subjected to diet of meat and bread, and nevertheless there is no glycosuria. There is no glycosuria because there is neither putrefaction nor fecal reabsorption. The operation of experimental diabetes in the dog is just what is necessary to guarantee a moderate digestion of carbohydrates; the sufficient one to realize the bacterial amylolysis, fermentation, and reabsorption. It is very probable that the action of putrefactive sugar will be the cause of superactivity or hydropic degeneration of the islands of Langerhans, because when this sugar is not produced the degeneration fails.

Brugsch,²⁷ who has made an exhaustive study of the different operative procedures of the pancreas—ligature of the ducts, extirpation, etc., upon digestion, and who discusses the interpretations of the results made by his predecessors, concludes from his extensive study that "the excision of the pan-

creas or its atrophy produces an extensive disturbance of digestion which cannot be attributed solely to the failure of pancreatic juice in the intestine. The disturbance shows itself by a diminished secretion, motion, and reabsorption in the whole intestinal tract, because the pancreas is a digestive organ, which through its secretion (hormone) or its nervous influence, or both, influences the entire intestinal tract."

Not only in the digestive organ but throughout the whole economy there is a real struggle for life between bacteria and the organism, all food which is not properly digested and absorbed is lost for the organism and gained for putrefaction. Overeating and rapid mastication overcharge the alimentary canal beyond its digestive capacity. The putrefaction increases and the noxious products of bacterial catabolism invade the organism and cause degeneration of the minute structure of the pancreatic gland. This process, a kind of vicious circle, goes on unnoticed until low carbohydrate tolerance appears, and later diabetes.

In accordance with the conceptions here established the pathogeny of diabetes mellitus is a fecal putrefaction and a fecal reabsorption of ammoniacal and acid character. Fully external and bacterial it is curable by bacterial and external methods, viz., prolonged fasting and restricted diet. Prolonged fasting has always been considered as the first of all measures to disinfect the intestinal tract. J. Méricourt² says: "There is a remedy more active than diet and purgatives which are not always free from inconvenience, for the renovation of the stomach, the small intestine, the large intestine, and the appendix in their organic integrity from the double point of view of disinfection and repair of tissues. This measure is absolute fasting for some days. But it is necessary that the fast be absolute, that is to say, that the privation of all solid and liquid aliment be absolute. For the washing out of the blood a mineral water may be permitted in sufficient quantity, or injection of mineral sera may be made during fasting. It is understood that the patient will remain in bed and avoid all movement as far as possible in order to prevent the waste of energy and promote repair. This fasting, somewhat painful the first day, is tolerated very easily later, and its duration should be eight days, as a minimum; to be efficient it may be prolonged up to ten or twelve days. This procedure can be varied in accordance with the loss of weight. The result of this practice is very notable; inveterate digestive disturbances are seen to disappear as well as gastroenteritis usually resistant to any form of treatment. Patients come from this period of fasting with their intestine disinfected, restored, entirely new."

As soon as the disinfection of the gastrointestinal tract has been obtained by this method, the *fundamental principle of the diabetic diet* consists in the adaptation of the digestive capacity to the quantity and quality of the food. A man who has become diabetic in consequence of his long-continued faulty alimentation and the loss of a part of his digestive capacity and injury to the pancreatic gland, has, nevertheless, some mechanisms remaining to aid in the digestion of carbohydrates. First, the small quantity of diastases his pancreatic juice contains. The diastases of his salivary glands, small intestinal juice, and large intestinal juice. The diastases secreted by the carbohydrate-digesting bacteria always present in his intestine. The diastases originating from the vegetable cells, and

finally the cellulases of bacterial origin. This last mechanism is of the greatest importance for the digestion of hemicelluloses and young celluloses. A diabetic can digest from certain legumes, salads, oatmeal, etc., up to 78.8 per cent. of the cellulose they contain. This digestion is of bacterial origin, but may produce cellobioses, sugar, and other available products. It has been also possible to prepare certain celluloses (from agar) which diabetics can utilize without increasing the amount of sugar in the urine. The importance of all this is that the diabetic can utilize a certain proportion of carbohydrates in the normal way, that is to say, without acid decomposition or disturbance of normal digestion.

Suppose, for example, that a diabetic, after his initial fasting, can digest daily 5 grams of starch and a certain amount of hemicelluloses without sugar appearing in the urine. Suppose this case is one of severe diabetes, but now progressing satisfactorily. Allen³ says: "Anyone can readily convince himself that, in a suitable severe diabetic who is symptom-free for days or weeks on a fixed diet, the addition of some quantity of butter or olive oil to the diet will bring back the glycosuria, ketonuria, and other symptoms immediately or within a short time. The feeding of fat alone does not cause glycosuria, and there is no proof that the sugar is formed from fat; most probably the sugar excretion results from the stimulating effect of fat upon metabolism. The overtaxing of the patient's metabolism by giving fat beyond the limit of tolerance may be an additional explanation of the failure of keeping certain patients free from glycosuria and ketonuria under former methods of treatment." In accordance with the theory of diabetes here described the fat diet increases directly fecal intoxication and reabsorption. The fat produces intestinal putrefaction and increases the quantity of acids and ammonia. The diabetic finds himself in the same condition as an experiment animal when bile is prevented from entering the digestive tube. Little disturbance ensues provided food is administered which contains but little fat. If fats, however, are given in large amounts, more or less serious digestive disturbances soon develop, and the animal loses weight. In such cases it has been ascertained that whereas normally from 2 to 10 per cent. of the ingested fat is eliminated in the feces, from 31 to 47 per cent. now escapes resorption. The offensive gases which are then passed by the animal are referable to an increase in the putrefactive processes in the intestine. This is, however, not owing to the absence of bile *per se*, but to the fact that the unabsorbed fat envelops the albuminous material and thus prevents its further digestion, so that in the lower portion of the digestive canal, where the putrefactive processes are most intense, the bacteria finds an increased amount of pabulum at their disposal, and an increase in the putrefactive products accordingly results. Thus, the presence of fat, in a defective digestive tract, increases the putrefactive processes. This is the fact. The relative quantities of ammonia and volatile fatty acids in stools following an albuminous and a fatty diet may be compared as follows (H. Fischer):

	Ammonia, Mg.	Volatile Fatty Acids, Grams
Albuminous diet.	608-576	2.88-1.70
Fatty diet.	939-1015	2.78-6.31

The return of acidosis and glycosuria is also easily explained. The cause is to be found in the fecal putrefaction and reabsorption: bacterial metabolism is what becomes impaired. This question is related to another experimentally studied by F. G. Benedict and E. P. Joslin,³⁰ namely, the metabolism of a healthy man subjected to the restricted diet of the diabetic. The studies upon acidosis have shown that the metabolism of health may be made to approximate closely that of disease by simple external influences, such as the withdrawal of all carbohydrates and the administration of large amounts of fat. Two persons—H. L. H. and H. H. A.—were subjected to a carbohydrate-free diet, and to the administration of much fat; in some instances they excreted 4 to 5 grams of β -oxybutyric acid per diem. The explanation of this change is simple: the production of ammonia and volatile fatty acids reaches its maximum in the large intestine, probably four times the quantities above stated are absorbed and transformed into urea and β -oxybutyric acid. The normal metabolism is unimpaired, but the bacterial metabolism is increased and the result of this is studied by means of the respiration calorimeter. A diabetic subjected to the same diet excretes a greater quantity of β -oxybutyric acid, acids, and glucose because the fecal putrefaction reaches a high degree and the greater part of the acid products of bacterial catabolism is transformed into sugar; this sugar is lost for the organism. The same phenomenon may happen in normal man in certain dietetic conditions, where a certain proportion of putrefactive sugar is formed when the fecal acidosis has surpassed the available bases there present. This excess of acid is transformed into sugar and this putrefactive sugar seems to be easily neutralized or oxidized by the action of pancreatic tissue, and finally disappears. The excess of acid, which is not of butyric origin in the diabetic, is also transformed into putrefactive sugar, a minimum proportion is decomposed, but the greatest part is eliminated. It is a fact that the diabetic organism cannot destroy β -oxybutyric acid or diacetic acid like the normal organism. It is also a fact that the diabetic organism cannot accumulate glycogen like the normal organism. Very probably both chemical actions are governed by the pancreas. Because of the destruction of pancreatic tissue and more especially the hydropic degeneration of the islands of Langerhans both these chemical actions fail. The normal pancreatic tissue becomes gradually exhausted fighting the consequence of normal constant intestinal putrefaction until finally diabetes is constituted.

When a normal man is fasting there is always a certain amount of feces produced and this stool contains always microorganisms. The dry solid of the stool amounts to 3.93 grams per diem. The proportion of nitrogen is 6.46 per cent. and 42 per cent. of this nitrogen is transformed into bacterial nitrogen. The relative proportion of bacteria is the following (Schmidt and Strasburger):

The healthy adult by test meal	5.3	grams of bacteria
A very restricted diet. 1 liter milk and 1-2 biscuits.	2.95	
A fasting man per diem	1.33	

In the fasting man the proportion of nitrogen in the stools reaches its maximum. The stool does not contain any carbohydrate and an anaerobic fermentation takes place in the large intestine. In this condition it is not surprising that a certain proportion of acetone should be produced by the reabsorption of butyrate of ammonia. When a

diabetic is fasting the excretion of a certain proportion of sugar into the intestine develops a certain antiketoplastic power, on account of the presence of the fermentative bacteria in the large intestine. Let us study this antiketoplastic power.

The perfusion of the liver by blood containing certain substances (Embsden) or the ingestion of the same substances by diabetics (Baer and Blum) have shown that the liver is the seat of the formation of acetone substances and there is a certain law in this formation. Acetic acid, propionic acid, and methylpropionic acid do not yield acetone. Butyric acid and other acid of hydrocarbon side-chains, directly derived from butyric acid, yield acetone, α - and β -methylbutyric acids, α - and β -ethylbutyric acids, but not α -methylvalerianic acid. Besides, all normal acids, superior homologues of butyric acid, with even carbon atoms, such as caproic, caprilic, capric, lauric, etc., yield acetone. All these acids in combination with ammonia give acetone when they are formed in the large intestine and pass directly through the liver by fecal reabsorption. For the production of these compounds an anaerobic putrefaction, such as may be produced by proteolytic bacteria, is necessary. If the meat and fat diet is changed and milk and sugar are taken, the proteolytic are substituted by acidophilic bacteria.³¹ The same thing happens if sugar is added to the culture media of *B. prodigiosus* or *B. typhi*, the production of ammonia decreases.³² Thus the carbohydrates modify the intestinal putrefaction and fecal products, and finally diminish the compounds that give acetone. This is the explanation of the antiketoplastic influence of carbohydrates when they appear in the intestines by excretion in diabetics, by ingestion, or by enema. They do not appear in the normal fasting man.

Notwithstanding the experiments in depancreatized dogs treated successfully with prolonged fasting and starvation diet against experimental diabetes the curative action of these measures is not clearly understood unless it is admitted that its action is produced by the disinfection of the intestine. On the contrary, the successful action of these disinfecting agents upon both experimental and human diabetes is a proof that the disease originates from some infection of the digestive tract.

Reasoning along these lines it is also easy to give a satisfactory explanation of the curative action of calcium upon glycosuria and diabetes, upon which Max Kahn and Moritz H. Kahn have recently called attention.³³ As has been established, diabetes produces a profound perturbation of the calcium and sodium metabolism of the organism, the two important opposite ions whose physiological equilibrium maintains the normal carbohydrate metabolism. The primary intestinal acidosis of putrefactive and fermentative origin engages the intestinal calcium in abnormal chemical combinations, unavailable for tissue metabolism and mostly eliminated in the urine. Consequently, the organism of diabetics lacks available calcium to counterbalance the glycosuric action of the predominating sodium ion. The fact is that the direct supply of assimilable calcium salts diminishes or makes disappear the glycosuria in the majority of cases.

Fasting and a very restricted diet are the best dietetic treatment of diabetes. But the radical treatment, both preventive and curative, is fecal disinfection. If diabetes is a disturbance of metabolism of bacterial origin the disinfection of the

intestine is the radical treatment. This may be obtained by different means: chemical antiseptics, surgical procedures, dietetic and hygienic measures, and biological antagonism. The biological antagonism ever present in the human intestine is the checking or retarding influence that the development of one species of bacteria has upon others. The best known and utilized antagonism of this kind is the checking effect which the acidogenous *Bacillus bulgaricus* produces upon putrefactive bacteria (Metchnikoff). In the tropical Atlantic region, the quantity of acid which exists in the feces is half the normal quantity which exists in the temperate zone, if determined by the same methods, and nevertheless in the former region there are many persons who reach an advanced old age in good health. This fact implies the existence in the tropical Atlantic region of some other form of biological antagonism than that described by Metchnikoff. The agent of this antagonism in the author's opinion is *Micrococcus oxycyanogenes*.¹ This bacterium attacks only the nitrogenous substances, it is not acidogenous, but is moderately ammoniacal. It produces a pigment, the *oxycyanin*, similar to the hemocyanin of poulp blood. The oxycyanin, colorless, but spontaneously turning blue when its solution is agitated in the presence of air, is not a noxious substance, not albuminous in character, and is resistant to heat and chemical influences. The *Micrococcus oxycyanogenes* owes its properties to this singular coloring matter above mentioned. When putrefactive bacteria develop luxuriantly on nitrogenous medium the addition of *Micrococcus oxycyanogenes* destroys all bad odor and noxious compounds in a few days. The methodic ingestion of this microorganism effects an absolute disinfection of fecal matter which becomes green and entirely odorless. The pigment produces the same effect more rapidly but less persistently. All putrefactive compounds disappear from the urine.

Arteriosclerosis is also connected with intestinal putrefaction and the reabsorption of putrefactive calcium salts. Prolonged fasting and restricted diet give the same good results here as in diabetes; but fecal disinfection is the main treatment of the disease.

118 EAST 116TH STREET, NEW YORK.

SMALLPOX AND VACCINATION.*

BY W. M. KENNA, M.D.,

CENTRAL VALLEY, N. Y.

ASSISTANT PHYSICIAN DR. MACDONALD'S HOUSE.

THE primary and essential object, it would appear to the writer, of the request for some remarks on the history of a disease with which you are all so familiar, was, very likely, to lull the auditors into a somnolent or lethargic state of mind and into a condition of inertia and anergy, so to speak, as a protection against the storm of discussion concerning smallpox which, if signs be true, may break out later in this meeting. For, in the matter of variola, the medical atmosphere in this vicinity is just at present surcharged with electricity of rather high potentiality.

Smallpox, it is generally accepted, existed in Eastern Asia long before its appearance in Europe. Up to Jenner's time it was always a devastating menace to society and, next to the plague, was the most fatal of all diseases to which the human flesh is heir. The history of smallpox, since Jenner's epoch-making discovery of vaccination, has had associated with it, even up to the present time, always the endemic growls and the periodic and acrimonious onslaughts of the antivaccinationists. The trials of the profession of yesterday, in this respect, are the tribulations of the present medical generation.

If Dr. Jenner were to appear before us today he would no doubt shake his head sadly and murmur: "Well, 'twas ever thus"; and, in all probability (such is the tenacity of purpose of some ob-

*Read before the Middlesex County Medical Society.

structionists to human progress) if he should again make an appearance a century hence, some such remark would still be pat and apropos.

The history of smallpox as related to vaccination since Jenner's time in spite of the fact that the disease still exists, may well be pointed to as an everlasting honor to the medical profession in its altruistic efforts to overcome and to stamp it out.

Those of us who have never seen a case of smallpox, or have never been intimately connected with an active and pestilential epidemic, little realize the horrors and trials of such a calamity. And were it not for the beneficent influence of vaccination, which has done so much to hold the disease in check, it had been the lot of many more medical graduates to study the disease at much closer range. Let the complaining wiseacres of the present generation pause for a moment in their whinings about the dangers of vaccination; and let them desist from their invidious sneers at the medical profession for its insistent and consistent encouragement of that prophylactic measure—let them, I say, in an open frame of mind turn back but a few pages of history and remind themselves that in the eighteenth century (not so many years ago) between fourteen and fifteen millions of people died of smallpox; let them recall, for instance, more specifically that during the years 1707-9 in Iceland, in a population of 50,000, this disease was responsible for the demise of 18,000 individuals; and, finally narrowing down to even a still smaller geographical area, let them cogitate upon the fact that in what was accepted as an unusually healthy town in England there was, at one period, only one person in fourteen of the population who had not had smallpox.

Let such examples be well digested—and many other examples of this type might readily be referred to—and let the minds of those opposed to vaccination carry, for the nonce, the images of these facts and allow the picture of the conditions existing since the inception of vaccination to be placed in parallel contrast, as it were. Then it would seem there could not reasonably be more than one opinion in regard to the merits and the benefits of vaccination with its successful antagonism to this scourge of humanity. And besides, even admitting the looseness of the much scorned statistics; even accepting a modicum of accuracy in this respect; and moreover, even not refuting the oft-quoted expression that "figures will lie," the evidence that since the introduction of vaccination there has been a great lessening of deaths from smallpox is overwhelming.

Take, for instance, the matter of mortality from the disease in children. It is a well-known fact that in nearly every country at the present time the children are vaccinated more generally than the adult population; that is to say, a relatively small proportion of adults is revaccinated. Now the death rate from variola among children before the introduction of vaccination was enormous. We see, during the period from 1580 to 1760, that of every thousand deaths, 961 were in children under ten years of age; again in the year 1774 in Chester, England, all of the 202 fatal cases were in children under ten. Still again, over 17,000 of some 36,000 deaths occurring in several places during the prevaccination period, were in children less than two years of age. These are facts in history. Smallpox was then, indeed, essentially a disease of childhood, like measles and whooping cough;

while today, it may be properly referred to more especially as an infection of adult life, this being due to early vaccination. In other words vaccination has practically eliminated smallpox as one of the expected physical vicissitudes to which those of tender years are susceptible; and it furnishes us, in a concrete way, with one of the weightiest and one of the most powerful arguments in favor of its continuance.
